Dr. George W. Duncan died September 8, at his home in Franklin, Ky., of cancer, at the age of eighty years. He was a graduate of the Medical Department of the University of Louisville in the class of 1847. One of his sons is a surgeon in the U. S. Army stationed in the Philippines.

Dr. James Laws died in Washington on September 11 in the seventy-eighth year of his age. He was born in Philadelphia and was graduated from the Jefferson Medical College in 1854. He entered the navy as surgeon and served until after the close of the Civil War, when he resigned. He practised then in Philadelphia, but in 1883 moved to Washington to accept the position of examining surgeon in the Pension Office, which he filled up to the time of his death.

Dr. William M. Late of Bridgeport, W. Va., died in Bordentown, N. J., on September 4, at the age of seventy-two years. He was born in Rappahannock county, Va., and studied medicine under his stepfather, Dr. William Duncan, taking his degree from the University of Pennsylvania in 1855. He practised continuously in Bridgeport to within a short time before his death.

Dr. Thomas Gilfilan of Northampton, Mass., died September 9 at the age of seventy-five years. He was born in Milton, N. Y., and was a graduate of the Berkshire Medical College in the class of 1854. He served in the medical corps of the Union Army during the Civil War.

Dr. Ernest Früh of Philadelphia died suddenly on September 7 at the age of fifty-three years. He was a graduate of the Jefferson Medical College in the class of 1876.

Dr. Colin P. Dewar of Ottawa, Ont., died September 7 of uremic poisoning at the age of forty years. He was graduated from the Medical Department of McGill University in the class of 1888.

## Correspondence.

### OUR LONDON LETTER.

(From Our Special Correspondent.)

THE BRITISH ASSOCIATION—PHYSIOLOGY—SOUTH AFRICAN DISEASES—CHEMISTRY OF GOLD—HEREDITY AND DEGENERATION.

London, September 1, 1905.

As the British Association (for the Advancement of Science, to give its full title) is meeting in South Africa, its proceedings seem scarcely to come within the province of a London correspondent. Yet those of us who remain in town are sufficiently interested to give to its doings even more attention than to the several vacation discussions that the newspapers have got up for our amusement or instruction. It will doubtless be for the benefit of South Africa, and we may perhaps say of this country, too, that a large amount of the attention given to the association has a great local interest. The event will diffuse knowledge which concerns us all on various topics, but I can only touch on one or two of medical interest.

Colonel D. Bruce in his presidential address before the Section of Physiology took for his subject the advance in knowledge during the last ten years of the causation and prevention of diseases of stock. South Africa, he said, was rich in the opportunities of studying diseases of animals, every species of domestic animal seeming to have one or more specially adapted for its destruction. The most important were East Coast fever, Texas fever, biliary fever of horses, malignant jaundice of dogs, tsetse-fly disease, trypanosomiasis of cattle, rinderpest, horse sickness, catarrhal fever of sheep, heart-water of sheep, goats, and cattle—quite a comprehensive list. East Coast fever was first recognized in the Transvaal three and one-half years ago, and proved excessively dangerous. Only about 5 per cent. of the cattle attacked recovered. The duration of the disease was about ten days. The cause was a minute blood parasite which lived in the interior of the red corpuscles and was carried by a blood-sucking parasite—the brown tick. No treatment will cure and no method of conferring immunity has been discovered. Texas fever or red water is found in almost all parts of the world, and was introduced into South Africa about 1870. The native cattle seem to have developed immunity for themselves, but, although apparently healthy, can communicate the disease to fresh importations—a great discouragement to the importation of prize stock—and there is no known way of conferring immunity which is free from risk.

As to the tsetse-fly, ten years ago it was supposed to kill by injecting poison, as snakes do. In 1895 Sir W. Hely-Hutchinson started an investigation which resulted in the discovery of the trypanosoma. Alone among the blood-sucking flies the tsetse-fly can convey the parasite from affected to healthy animals for at least forty-eight hours. The cause of this is not completely cleared up, but there is evidence of enormous multiplication of the trypanosomes

in the fly's intestines within twenty-four hours. Since 1895 many other trypanosome diseases have been discovered in all parts of the world, the most important being the "sleeping sickness" of the West Coast and Congo, which has spread to Uganda and other parts, and is still spreading and sweeping off thousands of human beings. No inoculation has proved of value as yet, and no drug has been of any avail. Rinderpest has lost its terrors since Koch's discovery, which was so well followed up by Kolle and Turner. It can now be stamped out wherever it appears. Horse sickness carries off thousands of horses every year. It only affects equines. But for it the Transvaal would be one of the finest horse-breeding countries in the world. No parasite has been found to account for it, perhaps because it is ultra-microscopic in size. No insect carrier has been discovered—no method of prevention or cure.

The President of the Section of Chemistry, Mr. G. T. Beilby, could scarcely avoid discoursing on gold production to a meeting in the richest of the world's gold fields. So, having described the process of washing alluvial deposits, he said that in 1889 it was superseded by the discovery of the cyanide process now universally employed. At that time probably not fifty tons of cyanide of potassium were produced in a year. Now the world uses little short of 10,000 tons a year, of which the Transvaal takes about one-third. Chemists must be interested in the production of the cyanide, as they are in the process of extracting the gold. Mr. Beilby, in discussing the chemistry of gold, remarked that Professor Liversidge said sea water contained a grain of gold per ton; but the weakest solution of cyanide was richer than that, so he was rash enough to predict that if the Transvaal mines were closed it would not be on account of the competition of the sea.

The debate on Heredity and Degeneration, opened in the *Morning Post* on August 14 by Dr. Archdall Reid, was closed yesterday. Quite a number of thoughtful writers have supported Dr. Reid's views, which, however, have failed to command the assent of the profession generally; and this fact perhaps led him to rather smart criticism of prevailing opinions. Medical men, he says, know that races exposed to adverse conditions, such as diseases, become inured to them, but they have no knowledge of any race which has grown degenerate in such conditions. Yet, he adds, they accomplish the surprising intellectual feat of believing that each generation under these conditions becomes more degenerate. This, he says, is as if they believed that walking down a hill would bring them to the top. Slum life, alcohol, disease, and so on have bulked largely in the columns of controversy which the *Post* has issued regularly for above a fortnight. In the long correspondence many smart things have been said, statements made and speedily contradicted, hypothesis put forward to have their bases cut away, and amid all prejudices expressed with the assurance that they were arguments. The most interesting part of the discussion relates to the conditions of slum life, and these are admitted to be what we usually call adverse. But would their removal arrest degeneration? It is urged that alcohol, for example, if banished to-day would reappear to-morrow. To be of any use, it must be got rid of forever; but this cannot be, and we must be content for evolution (blessed word!) to produce immunity; that we cannot alter human nature, and therefore the efforts of temperance reformers can only end in failure. This is so discouraging a notion to philanthropists that no wonder it has been opposed by an army of zealous men who are convinced that there must be a fatal flaw in the reasoning which leads to such a conclusion; and they have on their side facts in abundance, and many have been brought forward in this discussion. Some of them, especially those embodied in statistics, have been misinterpreted, and the bearing of others has apparently been misunderstood. In truth, all through this logomachy it has been difficult to dismiss the idea that the combatants are confusing the issues, and that, perhaps, more than anything by employing terms in different senses, though it seems also possible that neither side has studied the subject in some of its aspects.

The most common conclusion arrived at by readers will probably be that whether we are racially degenerating or not, it is the duty of the nation, if possible, to get rid of slums and all conditions adverse to the individual; and the majority hold that by doing this we may leave the race to take care of itself.

---

**Systematic Examination of the Eyes of Defectives.**—F. Park Lewis shows that the nutritive, psychic, and mental processes are all unfavorably modified by eyestrain. In view of this fact he believes every dull and nervous child, every person with incipient tuberculosis, every delinquent child, every applicant for admission to State hospitals, every epileptic with reasonable intelligence, is entitled to examination of the eyes for relief of this form of nervous waste if defect is present.—*American Medicine.*

## CAPITAL PUNISHMENT.

To the Editor of The Medical Record:

Sir:—I do not intend to discuss the legal phases of a question of such importance as this, but I want to bring before the profession my views on the necessity of changing the methods of capital punishment. Whether society determines to protect itself by eliminating its dangerous members instead of choosing the wiser course of educating them, thus eliminating their dangerous qualities, is a question for the jurist and the humanitarian. But the selection of the methods of causing death concerns us most particularly as the best interpreters of the psychological needs of humanity. If the punishment of a criminal is not a revenge by society, but only a protection, why should we cause death by a method producing physical and extreme mental suffering? What is the object of hanging or electrocuting the criminal? Do we realize the intense suffering of this human being while waiting to be called to the scaffold or electric chair? If we have decided to suppress this human being our sentence is a sufficient punishment, without adding the horrors of mental agony. Let us be humane! But aside from the interest for the criminal, against whom society would revenge her *læsa majestatis* and does not consider mercy the right of the murderer, does society forget that the criminal might have a mother, a wife, a sister, a child, and perhaps friends? Does society forget the condition in which these innocent beings connected with the criminal are while awaiting the execution of their loved one, and the nervous shock that the knowledge of the accomplished fact will produce? We do not know how many of these innocent creatures, especially women, enter the door of insanity after this period of apprehension and sorrow has passed, or the heritage of shattered nerves these women will bequeath if they have issue, thus perpetuating tendencies that will in time force additional obligations upon society. We do not know, and for that reason we do not care. Society wants to revenge itself, and calls this revenge "example." It is an example of cruelty for which we are responsible. Can anyone imagine the condition of mind during the time preceding the death of a loved one when capital punishment has been decided upon and is about to be brought into execution? Have we the right to impose such a strain on innocent people?

If the existence of capital punishment has not diminished the number of crimes, the adoption of methods more humane would hardly tend to increase them. Crime is less where the supreme penalty is not death; this is not the but established fact, proven by statistics and experiment—among other places in Italy, where capital punishment was abolished a century ago. The ancients were more merciful; the drinking of cicuta among the Greeks, and venesection among the Romans were methods of death adopted, and the person sentenced to die was compelled to be his own executioner within a certain time limit. It was humane and rational—not only using painless methods, but allowing the criminal to prepare himself for the last moment with an easy mind. If we do not want the criminal to become better while living, let us allow him to become better while awaiting death. There is no human being without a soul, and if during an entire existence this soul has not shown itself it may be these few hours of reflection before death will bring out the best and only good part of this soul. The best part of us manifests itself at the moment of passing. Let us allow everybody to think and reflect before death; it is a right to which they are entitled, and of which they should not be deprived. If the spectre of a cruel physical struggle is confronting the condemned we take from him all the possibilities of a rational death. While we are forced in this world, still we are responsible to a certain extent for our actions, but many times we are the victims of circumstances. Napoleon used to say that every soldier had in his knapsack *le bâton de maréchal*, and we might say that every man has in his brain the seeds of crime. It is simply a matter of circumstances and education. If we think it is necessary to eliminate the dangerous beings, let it be so; but let us be humane in so doing. We do not educate by terrifying and by keeping before the world this example of barbarity. We destroy without pity not only the criminal himself, but all the unfortunate creatures bound to him by human ties. The dreadful shock to them is not brought by the fact of death, but by the fact of inhumane death.

Not long ago I heard of a poor girl, daughter of a man who had been condemned to be hanged, asking the Governor of the State mercy for her father, saying: "Do not kill him; he is the only thing I have." What will this poor girl's life be if not a physical and nervous wreck? We know nothing about her; we have not watched her restless nights and her terrified visions since she knew that her father was going to be hanged; we do not see her frail body growing frailer and her tortured mind becoming weaker. We have obeyed the law and our tendencies, and we know nothing about the rest. Such a rationalism is

brute injustice; I only ask the legislator to take into consideration this fact, so little remembered because it touches the Pariahs of society—because it deals principally with those elements of society that, being kept by circumstances and by deficient intelligence in the lower strata, have no opportunity to be raised to our level. Surely it is time to relegate to the past, where it belongs, the old vengeful Mosaic law, "an eye for an eye, a tooth for a tooth." That we can find no way to punish crime except by crime is a grave indictment on our so-called civilization. Let us teach that we are punished by our errors, not for them; that the punishment for crime is surely fulfilled in the crime itself. Men will continue to kill one another until taught it is better for them not to do so; and killing them in turn does not teach them, nor has ever prevented a man from killing another when the fancied provocation was strong enough.

I have a deep and unfailing belief in the fundamental good in humanity. In each man there is an impelling instinct to progress, to mount higher, to be something more than he is. Often his very crimes may be a blind, ignorant following of this impulse for each man to endeavor to make the most of his life as he understands it. Let us be honest with ourselves. We are all deficient in some part of our character, and our boasted virtues are often the result of environment and physical organization. Shall we condemn to death the unfortunate wretch to whom Nature has given a brain in quality and quantity inferior to ours, and which the circumstances of life have defrauded of an opportunity to grow and expand?

Is it right for us to remain acquiescent and indifferent? Each and every man of trained thought and intellect has a vital responsibility toward his more unfortunate brethren, and should be ashamed to shirk his duty. The old question, "Am I my brother's keeper?" rings false now as ever.

Do we expect to educate the so-called criminal classes by showing so plainly that their directive minds, their natural protectors, are deficient in sentiment and knowledge which, all comprehending, is all merciful?

E. Castelli, M.D.

201 West Seventy-fourth Street.
New York.

# Progress of Medical Science.

*Boston Medical and Surgical Journal, September 14, 1905*

**The Modern Conception of Tuberculosis of the Skin.**—C. J. White makes two distinct divisions of tuberculosis of the skin. 1st, the true tuberculosis in which the bacillus of Koch can always be found in greater or less abundance, and in which animal inoculation always gives positive results; 2d, the tuberculides, in which bacilli are absent, but in which animal inoculations may often give positive results, in which the pathological picture is usually highly suggestive of tuberculosis and in which evidences of the disease, tuberculosis in some organ or tissue elsewhere in the body, can frequently be detected; and, 3d, a subdivision of the above second group in which we find a constitution prone to tuberculosis, one which exhibits the so-called tubercular diathesis of our forebears. The first class contains the well-known affections: lupus vulgaris; scrofulodermia, including tuberculous gummata, tuberculous ulcers, tuberculous lymphangitis; cutaneous miliary tuberculosis; tuberculosis verrucosa cutis; and lastly verruca necrogenica. The second class comprises the less known diseases: lichen scrofulosorum, erythema induratum, follicliis acnitis, acne scrofulosorum, acne cachecticorum, and morbilliform or scarlatiniform eruptions in the course of acute pulmonary tuberculosis. The third class includes, possibly, eczemascrofulosorum, pityrias rubra of Hebra, certain dyschromias, lupus erythematosus, angiokeratoma and lupus pernio. These various dermatoses of the first two classes are studied by the author in detail with reference to minute pathology and symptomatology. He admits that the diseases mentioned in his third class are in more or less dispute, because in them no one has ever been able to demonstrate any absolutely definite tuberculous process or to isolate from them the tubercle bacillus. Moreover, animal experimentation has invariably proven negative.

**Ocular Vertigo of Interest to the General Practitioner.**—The personal experience of B. P. Crott leads him to group cases of ocular vertigo under three heads: (1) that form seen in paralysis of the ocular muscle resulting from an interruption of the latter's nerve supply; (2) that form seen in paretic states of the ocular muscles or as he considers it preferably stated an "ocular muscle unbalance" and (3) that form accompanying refractive errors and familiarly known as "eye-strain." Illustrative clinical histories are given under each of these three classes.

*New York Medical Journal September 16, 1905.*

**Floating Kidney Due to Colon Displacement.**—The patient of S. Chandler was a woman aged 35 years, whose symptoms appeared after the birth of her only child. The symptoms present at the time of examination were the following: tinnitus; some expectoration of frothy mucus; attacks of palpitation of heart; pain in right side anterior below ribs; anorexia with periods of vomiting concurring with cardiac symptoms; flatulence and soreness in umbilical region; after an attack, headache and aching along right leg; frequency and hesitation in urination; depression and discouragement after an attack; bad leucorrhæa, bearing down pains, and pelvic discomfort; noticed at times a lump in the abdomen which she could, by pressure, move; stated that on some occasions she passed blood with urination. The attacks of cardiac, stomachic disorders, etc., appeared irregularly; on an average about every five weeks. The right kidney was absent from its normal site and was believed to be attached to the first portion of the large bowel. Abdominal incision revealed the kidney attached to the ascending colon and free in the anterior abdominal cavity. The bowel in being displaced by the pregnancy had drawn the kidney with it, and the peritoneum had gradually closed behind, carrying the vessels and ureter. The author comments on the impossibility of making an accurate diagnosis under such anatomical conditions. Operation consisted of opening the abdominal cavity posteriorly, replacement of kidney and bowel, care being taken not to twist the vessels, and suturing of the peritoneum so as to leave the organs one intraperitoneal and the other extraperitoneal. Recovery was uneventful, and all former symptoms disappeared.

**Epilepsy and Eye Strain.**—The brief paper of W. P. Spratling is an additional note to a contribution appearing in *American Medicine* April 9, 1904. It concerns a man whose epileptic seizures bade fair to cease after he had been fitted with glasses. The later history, however, did not bear out this promise. He went without seizures from September, 1902, till January, 1904. In the latter month his glasses were broken, and while not wearing them he had several attacks, four in January, six in March, and four in April. The six in March and the four in April occurred *after* he had again put on glasses. After April he had no more attacks during 1904, but they recommenced in January, 1905. In that month he had one; in February, five; in March eight; in April, four; in May, seven; in June, four, and in July, five. He had worn glasses constantly. The point to which the author wishes to call attention is that the glasses in this case seemed to *repress* the epileptic attacks in a manner not unsimilar to the repression that is often secured by the use of the bromides, and that like the bromides, while they may mitigate the disease, they are without power to cure.

**A Convenient Method of Leucocyte Counting, and the Value of this Sign in Appendicitis.**—E. L. Gros makes use of the following solutions: Aqueous solution acetic acid 5 to 1,000, 30 grammes; saturated alcoholic solution of gentian violet, 10 drops. For the count he prefers Hayem's hematimeter. In addition one must have a pipette for measuring 20 cubic millimeters of blood; also one for measuring ½ cubic centimeter of the acetic gentian violet solution. Another necessary accessory is a small glass-stoppered tube, containing about 1 c.c., in which the mixture is kept to be examined either at the bedside of the patient or at the doctor's office any time between one half hour to three hours after the blood has been drawn. The acetic acid dissolves the red blood corpuscles and the leucocytes alone appear in the microscopic field. The gentian violet is not strong enough to strongly color the whole leucocyte, but it makes the nuclei very visible and allows one not only to readily make the count, but also to rapidly determine the relative number of uninuclear and multinuclear cells.

**Mixed or Secondary Infection, With Some Consideration as to Treatment.**—E. A. Gray discusses this question in its relation to pulmonary tuberculosis, and gives the histories of seven personal cases. His special point as to treatment concerns the use of antistreptococcic serum. He has found records from 150 cases in which this remedy has been employed. In his own cases the serum seemed to be of benefit; but the small number of the patients and the fact that the benefits following the injections were only such as might have followed without them under the hygienic and other conditions maintained, make only a plausible but not conclusive argument for this adjuvant to treatment.

*Medical News, September 16, 1905.*

**A Test of Condition; Preliminary Report.**—The test advised by C. W. Crampton consists in the comparison of the systolic blood pressure and the heart rate of the recumbent with those of the standing position. It is well known that

variations of the combined area of the splanchnic system of vessels quickly show themselves in variations of peripheral vascular pressure. This splanchnic variation is caused not alone through the vasomotor nerves, but also through mechanical causes such as external pressure tone of abdominal walls, thoracic aspirations, and respiration. A long series of observations between the relative blood pressure of the standing and recumbent positions respectively gives the normal ratio of the healthy individual, and by comparison therewith it is possible to decide whether a given case is doing well or not. The method of taking the pressures is described in full. The therapeutically abdominal massage, abdominal construction exercise cause a rise in pressure by constructing the splanchnic area, while any factor causing a decrease in splanchnic tone such as warm baths, fatigue, disease, exercise (second stage leads to a lessened venous flow, a decreased output of blood from the area and a lowered pressure. Results are given of some interesting experiments along the foregoing lines.

**The Diagnosis and Differential Diagnosis of Pulmonary Tuberculosis.**—H. F. Stoll declares that paroxysms of coughing that are followed by vomiting are pretty apt to denote either whooping-cough or pulmonary tubercle. Some patients present but few constitutional symptoms while local signs are marked. As regards differential diagnosis, "malaria" so-called is often made the scapegoat, while chlorosis is the name often given to a group of symptoms which are really the onset of tubercle. Uncompensated mitral lesions often lead to hemoptyses which have nothing to do with tubercle. Cases of bronchitis persisting more than a few weeks and attended by emaciation, sweating, etc., are always suspicious. Acute tuberculous pneumonia having as it does an onset identical with that of pneumocous pneumonia is rarely diagnosticated at first. Sputum examination will settle the question.

**Rod Auscultation.**—This method of auscultation is explained by E. Reichman. A small rod is firmly applied to the surface of the body and the top of the middle finger passed with moderate force over the rod while the latter is steadied with the thumb and index finger. This friction produces in the rod vibrations, sound waves which, in accordance with well-known physical laws, are transmitted in every direction. Hence they pass also upon the surface of the body, and, if sufficiently strong, into the subjacent organs from which they are again transmitted in every direction. If then a stethoscope be placed near the rod, we can, with the ear applied thereto, hear these sound waves, and we note a sound of a peculiarly grating character, resembling somewhat the noise produced when a finger is passed over silk or similar material. If the skin is soft and not tense, the sound waves can pass through the same for only a very short distance. If they encounter an underlying contracted muscle, or, for instance, a rib, they will naturally be transmitted into the same, and, according to its course, continue in it, becoming audible nearly over the full extent of this muscle or of this rib, provided that both stethoscope and rod are placed over the same structure; an internal organ will, therefore, under these conditions, not be able to influence the audibility of the sound waves. But the conditions are different if a muscle or a rib does not intervene between the internal organ and the stethoscope and rod, or if either the stethoscope or the rod is applied so as to avoid a muscle or a rib. In this case, then, it is impossible for the sound waves to be transmitted through the latter from the rod to the stethoscope, and the examination of the internal organ is no longer disturbed thereby. We shall, then, since the sound waves are transmitted in every direction in this internal organ, hear the sound produced by them as long as stethoscope and rod are over this organ, and cease to hear them when one or the other has left the organ. Reichmann claims that by the method described it is possible to make out the boundaries of the internal organs far more accurately than is done by the methods usually employed.

*American Medicine, September 10, 1905.*

**The Treatment of Nonmalignant Strictures of the Rectum.**—Howard A. Kelly says painstaking prophylaxis should guide us in the treatment of rectal strictures situated in the distal portion of the bowel. Careful investigation should be made in all cases of so-called diarrhea and dysentery. The treatments consist in rest, diet, keeping the upper bowel emptied, cleansing solutions and applications, healing applications, and packs. A stricture of moderate caliber may be cured by dilation with bougies; by the elastic pressure of a rubber bag, distended by air, and made to distend in a uniform manner by a silk covering (Sweetnam's plan); and by digital distention and massage. If a contracting bowel is watched and treated, the patient may go on for a long time, for years even, in great comfort, though the disease is not cured. Resection of the bowel may be practised even when the disease extends over an area as long as 20 cm. A posterior incision with the removal of the coccyx, and sometimes of the last sacral vertebra, with the preservation of the anal sphincters and ampulla when possible, and an end-to-end anastomosis of the bowel, is the best procedure. It is sometimes worth while in the attempt to save the bowel when the local process persists in advancing to make an artificial anus completely diverting the fecal current. The bowel may then heal and the extensive surrounding inflammation undergo resolution, when, after some months or a year or more, and generally after a successful resection, the artificial anus may be closed. In a high grade of tuberculous or syphilitic stricture, when an extensive area is involved, it is often best to make an artificial anus and extirpate the diseased bowel. Kelly prefers to do this by first amputating the bowel above and ligating such hemorrhoidal vessels of the lower end as are within reach, and then completing the extirpation from below by an incision from sacrum to anus. Advanced tuberculosis always demands extirpation, and syphilis calls, of course, for persistent specific treatment, in addition to whatever local means may be employed.

**Therapeutic Value of Bactericidal Serums.**—Herbert D. Pease reviews some of the recently published statements of the clinical results obtained by the use of the various antistreptococcic serums in streptococcus infections, scarlet fever, rheumatism, and smallpox, and the antipneumococcic, antityphoid, antituberculosis, antidysenteric, antiplague, and antianthrax serums in their respective diseases. He calls attention to the variability in the reports of different writers on their results from the use of these serums, and the necessity for taking the personal equation into consideration in passing judgment upon such reports. He concludes that it is evident that in no one of the diseases considered has there yet been demonstrated an entirely satisfactory serum therapy. However, he thinks sufficient beneficial results have been obtained with some of the streptococcic, dysenteric, plague, and anthrax antiserums to warrant at least some hope of better results when our knowledge of these infections and their etiological agents has become materially increased.

**Gastrojejunostomy for Benign Stenosis of the Pylorus.**—William H. Morrison reports the case of a man aged 44 who came under observation when he was suffering from a sudden attack of severe hematemesis. He reported three previous attacks at intervals of about one year; in the intervening periods he was fairly well and able to work. There had been considerable digestive disorder with frequent attacks of vomiting. Examination showed marked dilation of the stomach, the greater curvature extending two inches below the umbilicus. There was no tenderness and no tumor could be detected. The contraction of the pylorus increased until apparently nothing passed into the intestine, all food taken being vomited after a longer or shorter interval. The abdomen was opened in the median line and a communication established between the posterior part of the stomach and the jejunum, four inches from the duodenojejunal fold, a large-sized Murphy button reinforced by a continuous peritoneal suture being employed. Recovery was uneventful.

**Emotional Shock and Fright as Causes of Epilepsy.**—According to W. P. Spratling emotional shock and fright as causes of epilepsy do not receive the attention they should. Epilepsy may supervene immediately after the application of such a cause or be delayed for some time. The reapplication of the primary cause often induces successive attacks similar in nature. Predisposition usually exists in all such cases. In 1,323 cases the author found emotional shock or fright to have been the cause in 62, equal to 5½ per cent. Of these 22 were males in a total of 814, and 40 were females in a total of 500, being 3 per cent. of the former and 8 per cent. of the latter. This shows such causes to be nearly three times as active among men as among women. This greater susceptibility in women is present from childhood. During the first ten years of life there were 14 cases due to this cause among 814 males, and 15 among 519 females. After the twentieth year there was only one case in either sex. It appears from the studies in question that emotional shock or fright most often leads to epilepsy in the female sex and that they are most apt to be active about the age of puberty.

*Journal of the American Medical Association, September 16, 1905.*

**Colohepatopexy.**—E. Wyllys Andrews disagrees with R. T. Morris as to the cause of unpleasant symptoms from adhesions following gallstone operations; he has seen no cases of angulation of the cystic duct or of apparent dragging on the sympathetic nerves; the trouble he has seen has always been from gastric disturbance, and then only when the anterior wall or one border beyond the pylorus was involved. He, moreover, does not believe in the efficacy of Cargile membrane or of aristol to prevent the reforming of these adhesions. He does not consider them

disadvantageous in themselves, but only so on account of their situation, and the method he has devised for the relief of the symptoms is based on the possibility of their replacement in a more advantageous position. After carefully separating the adhesions, he pulls up the transverse colon, with any loose omentum that may be present, into the space between the liver and pylorus, and stitches the omenta to the gastrohepatic ligament, liver surface, or such adhesions as form the angle between pylorus and liver. Five patients thus operated on are reported, and he summarizes his conclusions as follows: "1. Gall-tract adhesions are inevitable after disease and operation. 2. They are beneficent, harmless, and symptomless in all but a few cases. 3. These few represent malposition rather than trouble from adhesions *per se*. 4. The colon, gall bladder, duodenum, and pylorus can adhere to each other without impairing their function. The other parts of the stomach cause trouble if involved. 5. Such adhesions will reform when separated, unless the colon be substituted for the stomach. 6. The causing of colon adhesion to the liver does not perceptibly disturb its function. 7. Probably certain vague gastric disturbances have been treated by gastroenterostomy when the patients would have had more benefit from this operation."

**Treatment of Antral Disease Through the Nose.**—In cases of antral empyema, G. L. Richards would first determine whether the case is of dental or nasal origin. If the former, he would treat it accordingly, but would not continue, by tube or otherwise, any lengthy course of treatment through the mouth. If of nasal origin, determined by exploratory puncture if necessary, he would see whether simple washing out of the antrum through the natural opening in the nose might not be sufficient to produce a cure. If not, he would endeavor to secure better drainage by making an opening below or above the lower turbinate, or both below and above. It is desirable to make the opening low for better drainage. He prefers not to remove any of the lower turbinate bone unless it is enormously large and swollen, and usually a sufficiently large-sized opening can be made above or below it. The opening can be enlarged sufficiently to permit packing with gauze, and a good portion of the mucous membrane can be curetted. If there is polypoid degeneration, or if the condition does not improve after a reasonable trial of this method, any purely nasal treatment will fail, and the radical operation by way of the canine fossa and removal of the entire mucous membrane of the antrum will be required. Most patients, however, can be treated successfully through the nose. If necessary, the anterior portion of the middle turbinate can be removed to make a larger opening, and if a tooth is in the way it can be removed without abandoning the nasal method of treatment. Note also should be taken as to whether there is an empyema of the frontal sinus draining into the antrum. The nasal method does not in any way prejudice further operations if found necessary, but, rather, prepares the way for them. Several cases are briefly reported.

**Uncomplicated Tropical Amebiasis.**—W. E. Musgrave discusses the subject of tropical amebic dysentery under four heads: 1. Latent and masked infection. 2. Mild and moderately severe forms. 3. Severe cases, including gangrenous and diphtheritic ones. 4. Infection in children and in the aged. He gives the symptoms, and reports briefly two cases illustrating the insidious nature and the lack of characteristic symptoms in the latent type. The mild or moderately severe cases form the great majority of those seen in Manila at the present time, and most of these develop from the latent cases before mentioned. If early recognized and properly treated, they rarely pass beyond the diarrheal stage, and many, even without treatment, never become dysenteric in the common acceptation of the term. The severe cases develop from these and from the latent ones and their characteristics are well known. Children and old people seem to manifest a decided natural immunity, but while in children the infection, when it does occur, usually is of a mild type and very amenable to treatment, the reverse is true of the aged. A striking peculiarity in both classes, as well as in Filipino natives, is the absence of liver abscess. Musgrave has not seen a case of this in a thousand clinical cases, and one hundred autopsies of natives of the Philippine Islands. The chief point made in the article is that the disease manifests itself in a much broader and more comprehensive clinical picture than that generally allotted to it. Waiting for actual dysenteric symptoms before making a diagnosis, he thinks, is responsible for a large percentage of the present mortality from this cause in Manila. Bloody stools may occur early, but usually are not seen until considerable damage has been done, and may be absent till near a fatal termination or recovery. Prompt treatment of every patient in whom motile amebas are found, without waiting for clinical dysentery, is the safe course to follow.

**Thyroid Disease in California.**—H. C. Moffitt writes on thyroid disease in California. Observation has convinced him that thyroid disease is more common in San Francisco than in many other cities, and he has studied the subject by correspondence with other physicians throughout the state. Goiter is more common, especially about San Francisco Bay, and less frequent in the southern part of the state and in the mountains, and is endemic in certain portions of the northern section. Myxedema seems to be more frequent in San Francisco, perhaps because most patients drift there. He has reports of 53 cases in that city and 33 throughout the state, excluding *formes frustes*, of which he has notes of 11 cases. These are characterized by dry skin, scaling of the scalp, thinning of the eyebrows and loss of hair from the neck and in the axilæ, pains in the knees and ankles and between the shoulders, and fat pads about the upper back and clavicle are characteristic. Of sporadic cretinism, he has collected 61 cases altogether, 35 of them in San Francisco. Exophthalmic goiter seems to be much more common in Bay counties than elsewhere in the state, and he remarks on the danger of the use of the iodin preparations, especially when a goiter exists, however small. He has had several cases of iodism in patients with small goiters, and he suggests the possibility of the strong sea winds in San Francisco affecting the frequency of cases. The therapy of thyroid conditions is discussed at some length. The reports as to thyroid medication in myxedema and cretinism are enthusiastic; large doses are not required, and they may produce unpleasant symptoms in myxedema. He has seen good results in exophthalmic goiter from long-continued faradism. He thinks many cases of exophthalmic goiter are amenable to surgery, and that more attention should be given to the statement of Horsley that division of the isthmus alone leads to retrogressive changes and shrinking in the rest of the gland.

**Objectionable Advertising.**—C. S. N. Hallberg, H. W. Wiley, and H. C. Wood, Jr., give accounts of cases illustrating fraudulent claims of patent medicines, complexion powders, etc., and notice certain rulings of the Postoffice Department and of the law officers of the Government. For a time the Postoffice Department prohibited the sending of poisons through the mail. Influence has been brought to bear, however, and the ruling was changed so that it is possible to send any poison through the mail, provided it carries the label or superscription of the manufacturer or dealer. The authors call the attention of the Department to the fact that in almost every State poisonous remedies must be marked with poison labels indicating their dangerous character, and it would be well for the Postoffice Department to follow their example. The ruling of the Department of Justice in regard to the withdrawal of mail privileges is rather loose, and many fraudulent medical concerns are working under it with impunity. The difficulty of obtaining legislation to mend the matter is chiefly in the fact that many of the senators and representatives are themselves the dupes of these concerns, believing that their wares really have some virtue.

*The Lancet, September 9, 1905.*

**The Pathology and Treatment of Eclampsia.**—J. W. Byers declares that the old theory of causation of eclampsia, viz., that it depends on poisoning of the nerve-centers by certain by-products which the kidney fails to eliminate, tendency to look upon the liver as the faulty organ, for autopsies in fatal cases have shown a pretty constant occurrence of irregularly-shaped red or white areas of necrosis caused by degenerative changes following thrombosis of the smaller portal vessels. A second theory is that eclampsia results from the accumulation and non-elimination of toxins manufactured by mother and fetus, but no one has ever been able to isolate the setoxins, and scientific proof of their existence is still wanting. We do not yet know why eclampsia is so common in primiparæ, especially the young and the old, why it is more common in some districts than in others, why it is more common in certain years, and just what part in the production of the malady is played by the fetus. The author's views on treatment are thus summarized; Assuming that the attack cannot be averted (1) Treat the convulsions with morphine used subcutaneously. Keep the patient on her side, purge freely in the method recommended, use saline infusion, allow no liquids; in a word, as Gooch advised long ago, "take care of the convulsions, and let the uterus take care of itself." (2) Make an effort to eliminate the poison by purgation, hot packs, and by saline infusion. (3) If labor has not set in treat the convulsions but do not induce premature labor of the uterus. If labor has begun and the patient is in the second stage and the os dilated give chloroform and deliver by forceps if possible, or by turning. If, however, morphine and purgation with saline injections have been tried and the patient is not improving, dilate the cervix and deliver. (4) For the convulsions after delivery use morphine, purgatives, and saline infusion. (5) In the prophylaxis of eclampsia, rest, milk diet, warm baths, and purgatives are the best methods.

**One Hundred and Twenty-nine Consecutive and Successful Operations for Appendicitis During the Quiescent Period, in Twelve Years.**—J. L. Thomas writes interestingly of his personal experiences. For five years up to 1898 he operated under wet antisepsis, but since then has followed the dry aseptic plan, both operator and assistants wearing thread gloves, and gauze pads replacing sponges. Two facts have impressed him as the results of this change of method: first, that shock and reaction after operation is very much less under dry aseptic methods, due in some degree to the fact that the patient's system is not poisoned by the absorption of carbolite or bichloride, and, second, the disappearance of suppuration and stitch abscess. Formerly the abdominal wound was closed by sutures *en masse*, now with buried sutures, the number of layers varying with the thickness of the abdominal wall. Dressings are discarded, the wound being sealed with gauze and collodion. As a rule, patients are allowed up in from eight to twelve days after operation. The author advises the removal of the appendix in cases of, first, operation for ventral hernia following the opening of a perityphiltic abscess, and second, persistent thickening or induration after a first attack of appendicitis. Occasionally he has removed, at the patient's request, the appendix after the first attack has run a normal course, and he advises its removal after two definite inflammatory attacks. In one case he found instead of appendical inflammation a salpingitis simulating enteric fever, and in another concretions in a misplaced appendix, simulating persistent biliary colic.

**Family Tabes Dorsalis.**—E. F. Trevelyan records an instance in which this disease was present in husband, wife, and daughter in the same family. The husband showed symptoms at 33 and died at 58. The wife, now living at 55, was married at 19 and showed symptoms at 29. There was a practical certainty of syphilitic disease. The daughter first showed symptoms at 27 and is now living at 43. The author has been able to find but very few recorded cases of tabes in husband, wife, and offspring. Sometimes general paralysis has replaced the tabes in one of these family groups. Cases of tabes in one parent and offspring are fairly numerous. The acceptance of the theory of syphilis as the cause of the disease in the child does not imply that the latter must necessarily bear the stigmata of congenital syphilis. Trevelyan says that in his own cases the question may be fairly put in the following form. Did the tabetic couple merely hand down to their daughter a general vulnerability of nervous tissue to certain noxæ (whether in the form of the syphilitic virus or stress, strain, etc.), or did they transmit to her the actual virus which would bring about with little or no further provocation the eventual degeneration of the afferent sensory neuron? He is inclined to the latter hypothesis.

*British Medical Journal, September 9, 1905.*

**Remarks on Poisoning by Fungi: Amanita Phalloides.**—Charles B. Plowright declares that the majority of fungi may be eaten without consequent illness, provided they are suitably cooked. The really poisonous species are very few in number. The particular species which causes so many deaths owes its lethal power not to an alkaloid, but to a toxalbumin-phallin. This fungus is *Amanita phalloides*. In France alone eighteen deaths have been traced to this fungus and its varieties since 1900. The period which usually elapses between the ingestion of the fungus and the appearance of the first symptom averages between ten and twelve hours. In the cases referred to above, the average period in which it proved fatal was seventy-two hours. The six cases treated by atrophine proved fatal, as did the three others in which belladonna was given. Half of the cases were under twenty, and a third under ten years of age. Phallin is very similar to the toxalbumin ricin contained in the seeds of the castor-oil plant, and abrin in the scarlet and black beans of *Abrus precatorius*—jequirity. The most common symptoms of poisoning from the ingestion of phallin are, vomiting not occurring for several hours after the fungus has been eaten, diarrhea, pain in the abdomen, cramps of the stomach and diaphragm, intense thirst, cold sweats, collapse, sometimes headache, delirium, more or less complete suppression of urine, slight but distinct jaundice in the latter stages of severe cases, subnormal temperature, and sometimes cramps in the limbs. The post-mortem signs are absence of rigidity, marked hypostatic discoloration, inflammation of the gastrointestinal mucous membrane, localized ecchymoses of the liver, alimentary canal, pleura and lungs, enlarged solitary glands, fatty degeneration of the liver, fluidity of the blood and hyperemia of the meninges. The stomach and intestines should be emptied in those cases only which are seen in the early stage. A dose of castor oil may be required. Morphine is almost always required to relieve the intense suffering. It has been suggested that permanganate of potassium will decompose any phallin left in the stomach. The subcutaneous administration of normal salt solution has been successful. In the recognition of these plants, it must be remembered that Amanita phalloides is never anything else but white beneath the cap, where the mushroom is pink, purplish-brown or almost black. On the top phalloides is often nearly white, though there are nearly always traces of yellowish-green, especially about the margin. Its stem is always bulbous and has a cup-like base. The stem of the mushroom is nearly cylindrical. Phalloides never grows far away from trees, especially oak trees. One further point about this poisonous plant should be remembered: it will "peel" almost as well as the common mushroom.

**A Case of Empyema of the Gall-Bladder, with Unusual Symptoms.**—R. Atkinson Stoney calls attention to the general statement that the dullness caused by a tumor of the gall-bladder is continuous with the liver dullness, and that the intestine is never situated in front of an enlarged gall-bladder. He reports a case of empyema of the gall-bladder, the result of the obstruction of the commencement of the cystic duct by a calculus. The liver was enlarged so that the anterior edge reached almost to the level of the umbilicus. A dull percussion note, however, was obtained for only one and one-half inches below the costal margin. The tumor was situated below the level of the umbilicus. The transverse colon was adherent to the under surface of the liver between its anterior sharp margin and the fundus of the gall-bladder, causing a resonant note to be obtained on percussion between the hepatic dullness above and the gall-bladder dullness below. On account of these unusual signs a wrong diagnosis of appendicitis was made. At operation it was found that both appendix and cecum were normal. A perforation in the neck of the gall-bladder was found. About four ounces of pus and mucus which welled up in the wound were swabbed up. The neck of the gall-bladder and cystic duct were freed, ligated, and divided, and some strips of gauze were passed down to the bottom of the wound. After its removal the gall-bladder was found to have a capacity of four ounces. The wall was nearly one-half cm. thick, and was very soft and friable. There was a small perforation in the neck, and a soft, round stone was discovered in the commencement of the cystic duct. The fluid in the fundus of the gall-bladder was a clear, thick mucus, but in the neck of the bladder was a thick, odorless pus of a light greenish color. The infection was proved to be one of the bacillus coli communis.

**The Rational Treatment of Capillary Hemoptysis in Phthisis.**—Charles Gaskell Higginson as a matter of routine, in treating the morning hemoptysis of phthisis, considers hypostatic congestion as the root of the evil. He still tries to quiet the cough and keep the bowels moving, but he has renounced hamamelis and ergot, and depends upon altering the patient's position from the supine to the semi-sitting—an angle of between thirty and forty-five degrees with the horizontal plane—by day and by night. He believes this to be the far more rational and effectual method of treating such cases. His experience has convinced him that the supine attitude is a strongly predisposing cause of the blood-spitting. In these cases the writer uses a bed-rest padded with stout pillows.

**Infantile Convulsions.**—J. Reid quotes Churchill's statement that anemia is probably the first state of the brain in convulsions. A hot bath with cold affusion to the head would bring blood to the surface of the body and probably still further deplete the brain. Post-mortem there are ischemic states in liver and brain, and the writer declares that he considers the bath of doubtful utility. He concludes by saying that the occurrence of convulsions is probably due to the unequal distribution of blood in the system, caused by inflamed foci in many cases. In his hands poultices to consolidated lungs with suitable treatment have given good results. Baths are successfully used in reducing temperature, but caution is necessary in their use. He believes that further inquiry is necessary to determine whether the cause of death in such cases is to be sought for in the unstable nervous system of the child or elsewhere.

*Berliner klinische Wochenschrift, August 28, 1905.*

**The Elastic Tissue of the Stomach Wall, and Its Relation to the Pathology of the Stomach.**—Mironescu ascribes an important part to the elastic tissue present in the gastric wall in the maintenance of the normal motility of this organ. This tissue is distributed in two bands. One lies in the form of a network between the fibers of the muscularis mucosæ, sending prolongations between the glands along the blood vessels supplying the mucosa. The other layer lies between the submucosa and the muscular coat of the stomach in the form of a distinct membrane. In a seven months' fetus these two strata were already differentiated. The function of the internal layer of elastic tissue is to furnish a support for the contraction of the muscularis mucosæ: that of the outer layer is to prevent excessive dilatation, and through its elastic char-

acter to enable the stomach to resume its normal form after the changes due to the contraction of the muscular coat. The elastic tissue is least highly developed at the fundus, the point, namely, in which the contractions are least forceful. To the congenital non-development of the elastic tissue the writer attributes some of the cases of disturbance of motility for which no cause can be ascertained. That such a congenital deficiency can occur is shown by the examination of stomachs of fetuses. Atony and dilatation of the stomach, either acute, occurring after dietary indiscretions, or chronic, without stenosis of the pylorus are also traceable to this abnormal condition of the elastic tissue. Where such conditions obtain operative interference naturally yields incomplete relief, unlike the cases of dilatation secondary to pyloric stenosis in which the elastic tissue is but secondarily affected. On the other hand, the writer's theory explains the efficacy of a cure based upon the limitation of the amounts ingested. Over-distention is thereby prevented, and the stomach thus enabled to regain its normal form.

**Some New Theories of Cardiac Neuroses and the Superposition of Dilatation upon Them.**—Franze deals in this article with cases of dilatation of the heart occurring in young and middle-aged adults, and dependent pon cardiac neuroses. Sexual neurasthenia preceded the cardiac disturbance in all the writer's cases. The de rangement of the nervous system in neurasthenia may lead to abnormalities in metabolism in consequence of which the nutrition of the heart and its ganglia suffers. The result is arhythemia and lessened power of contraction. But the heart may also be affected through the nerves distributed to it; viz: the vagus and branches of the sympathetic system. Of the cardiac neuroses, paroxysmal tachycardia depends directly upon a paresis of the vagus. Reflex digestive neuroses and bradycardia arise from disproportionate activity in the inhibitory and stimulating vagus centers. The association of sexual neurasthenia with cardiac neuroses is explained by the intimate relation of the sympathetic system with the genitourinary organs, and in affections of these viscera the cause of functional cardiac disease is most often found. Whether the neurosis is due to disease of the cardiac ganglia, the vagus or the sympathetic nerves the result is a muscular insufficiency preventing the complete emptying of the ventricle during systole. Under the pressure of the blood not ejected into the arteries, the heart wall gives way. That this is a dilatation and not a hypertrophy is proven by the disappearance of the enlargement under appropriate therapy. The treatment consists in the regulation of the diet and in electrotherapy. Most efficient are the alternating current and galvanic baths, together with $CO_2$ baths.

**The Hemorrhagic Form of Cirrhosis of the Liver.**—v. Aldor groups under this name those cases of hepatic cirrhosis in which the most prominent symptom is recurrent hemorrhage appearing in the preascitic stage. In two of the cases reported by the writer the bleeding proceeded from the stomach, in a third from the intestine; in the fourth from the nose. A hepatic and a splenic tumor were present in all the cases, but the symptoms of the later stages of cirrhosis—ascites, diarrhea, meteorismus—were lacking. The hemorrhages appeared without premonitory symptoms, or were preceded by mild digestive disturbances. The amount of blood lost may be sufficient to cause exitus, or, as in v. Aldor's intestinal case, small amounts of blood may be constantly present in the feces. A rapid recovery after the hemorrhage is characteristic, but a high grade of anemia persists. Owing to the obstruction in the liver a collateral circulation is established between the portal system and the vena cava inferior through the esophageal and gastric vessels. These vessels are in a varicose condition, and the sudden hemorrhage is due to rupture of such a varix. In the intestinal hemorrhage the blood probably proceeded from a hemorrhagic erosion following inflammation and neurosis. The anatomical lesions are identical with those in the ordinary form of cirrhosis and in the so-called Banti's disease. v. Aldor believes it not impossible that his cases may be a form of the latter

*Munchener medizinische Wochenschrift, August 29, 1905*

**The Formation of Specific Antibodies in the Host of Tæniæ.**—Langer tested the blood serum of two series of cases, one of normal and diseased individuals not infected with taenia, the other of patients in whom either taenia mediocanellata or taenia saginata had been determined, with an extract made by rubbing up T. mediocanellata in salt solution. In no instance was a precipitate formed. From a rabbit injected subcutaneously with 100 c.cm of such an extract in divided doses a serum was obtained that in a solution of 1:15,00 gave a precipitate not alone with the extract of T. mediocanellata, but also with that of T. solium. T. cucumerina and ascaris lumbricoides. Even with this immune serum, however, the blood serum of patients, the hosts of tæniæ, gave no precipitate. Equally negative results were obtained with the blood serum from a case of echinococcus infection, while with the fluid from one of the daughter cysts a precipitate was present in a dilution of the serum of 1-80. Langer believes that this reaction may be utilized in establishing a diagnosis of echinococcus infection when the absence of hooklets and scolices leaves the observer in doubt. Langer is unable to corroborate the conclusions of Fleckseder and Stejskal that homologous immune serum exerts an inhibitive action upon the tæniæ. He further demonstrates the inability of these cestodes to assimilate heterogenous albumins among which the antibodies must be classified. The introduction of an immune mediocanellata serum either subcutaneously or directly into the duodenum of dogs infected with tænia also gave negative results. The writer therefore concludes that such an immune serum possesses no therapeutic value.

**A Mild Type of Phlegmon Ligneux.**—Fichtner describe a series of cases characterized by the sudden appearance of a firm, hard mass on the submaxillary region, due to the enlargement of the cervical lymph-nodes, and in some cases to inflammation in the periglandular tissue. The swelling is neither painful nor tender. The course of the disease is subacute, extending over an average period of two months, and ends in resolution without the formation of an abscess. In two of the cases the tonsils were simultaneously inflamed, in one other a mild gonarthritis was present. Constitutional symptoms were confined to a mild, irregular temperature that was not a constant feature in all the patients. The nodes of both sides were affected, but one side was always more extensively involved than the other. Etiologically Fichtner considers the inflammation to be caused by the entrance of an organism (streptococcus, staphylococcus) of diminished virulence through the tonsil or through a carious tooth. The occurrence of rheumatic inflammation of the knee in one case, of a preceding facial erysipelas in another, and of tonsillitis in still two others seems to support this view. From the typical phlegmon ligneux of Reclus this disease differs only in the suddenness of its onset, its mild course, and the lesser involvement of the subcutaneous tissues. Therapy exerts no apparent influence upon the course of the infection.

**The Etiology of Carcinoma.**—Fuchs bases his theory of carcinoma upon an abnormality in the physiological cornification and desquamation of the epithelial cells of the skin and mucous membranes. The fixed cells of the corium send prolongations between the cells of the stratified epithelium; wandering cells are also found in the same situation. Both the fixed and wandering cells are capable of producing fibrin. Under the stimulus of irritation this fibrin may be thrown out in considerable quantities, while at the same time the cells themselves proliferate, forming a layer of granulation tissue between the germinative and other strata of the epithelium. The ultimate result is a fine scar. Normally the cells of the germinative layer are constantly proliferating, the older cells being pushed toward the surface where, under the influence of the fixed and wandering cells, their protoplasm undergoes a change resulting in the cornification of the cell. The presence of the fibrin, granulation tissue, and fine scars just described offers a hindrance to the advance of the young epithelial cells toward the surface, and they are pushed along the path of least resistance; *i. e.* into the lymph spaces of the corium, where further unitotic division occurs.

---

**An Error to Be Avoided in the Diagnosis of Ascaris Lumbricoides.**—De Nabias calls attention to the fact that in certain cases the pollen grains of the artichoke, when found in the stools, are mistaken for the eggs of the ascaris lumbricoides. He then gives the differential points to be observed in making the diagnosis. The pollen grains are all very similar. The shape is regularly spherical in place of being variable—sometimes round, sometimes ovoid, sometimes elliptical, as is the case with the pollen grains as found in the stools. The dimensions of the pollen grains are uniformly 45 μ by 45 μ. As to the eggs, the dimensions vary with the form. It must be remembered, however, that the round eggs have the same measurements as the pollen grains. In such a case when any doubt arises, the color reaction should be the test. A saturated solution of fuchsin in alcohol decolorized by ammonia, is used. By it the pollen grains are instantly colored a vivid red, especially noticeable in the center. The peripheral part preserves a blackish aspect. The eggs, however, when placed in this solution, are not colored but they break up under the action of the ammonia, allowing either a part or the whole of the contents to escape. The differences between these reactions are very definite.—*Journal de Médecine de Bordeaux.*

# Book Reviews.

A Text Book on the Practice of Medicine. For Students and Practitioners. By James Magoffin French, A.M., M.D., Formerly Lecturer on the Theory and Practice of Medicine, Medical College of Ohio. Second, Revised Edition. Illustrated by 11 full-page plates and 50 wood engravings. New York: William Wood & Co., 1905.

The second edition of this valuable text-book is much like its predecessor in size and arrangement. The author has wisely placed the acute infectious diseases in a group, arranged clinically rather than from the etiological standpoint. The additions to the work have been brief and to the point, and include such topics as actinomycosis, the Leishman-Donovan bodies, and trypanosomes. In short, the volume has been brought fully up to date and represents a work which is particularly fitted for students on account of the conciseness, simplicity of language, and the author's capacity for imparting knowledge. The arrangement of the work fits the lecturer's needs as well, there being a preliminary section on the principles of medicine in general; followed by chapters on the infectious diseases, and diseases of the different systems and organs. The final portion is given up to clinical methods of examination, including blood, stomach contents, intestinal discharges, urine, and bacteria. For a one volume text-book, portable and readable, it contains an unusual amount of accurate and helpful knowledge, and can be recommended without hesitation.

Paralysis and Other Diseases of the Nervous System in Childhood and Early Life. By James Taylor, M.A., M.D., F.R.C.P., Physician for Out-patients to the National Hospital for the Paralyzed and Epileptic, Queen Square; Physician to the Northeastern Hospital for Children, and to the Moorfields Eye Hospital. Philadelphia: P. Blakiston's Son & Co., 1905.

The author of this work has done well to mark off from the great subject of neurological pathology those affections of the nervous system to which children are especially prone. It may be objected that this is carrying the principle of specialism too far, but we think not. The pediatrist should of course have studied the diseases of the nervous system in general and should be familiar with the basic principles of neurology, but in his daily work he has occasion for special knowledge of the diseases of the nervous system as they affect his little patients more particularly. It is in meeting the wants of such as these that the book finds its justification. The several chapters deal with meningitis, paralyses of cerebral origin, intracranial tumors, chorea, and allied diseases, diseases of the spinal cord, and "other diseases," under which indefinite title are included convulsions, night terrors, epilepsy, cretinism, achondroplasia, microcephaly, and various other affections incapable of classification under the other heads. In treating these subjects the author notes particularly the points wherein the disease as it occurs in the child differs from that in the adult, when the affection is one common to all periods of life. The illustrations are quite numerous and good. One most commendable feature of the book is the absence of references to the literature. It appears to be a failing of neurologists especially to back up all their assertions with long lists of authorities, as though they feared their unsupported statements would be disputed. That gives an appearance of compilation to much of their work, which detracts greatly from its interest, if not from its value. The present author has discarded all such props, and one reads the book with the feeling that he is getting original views based upon the author's own experience. It is much more pleasant, and the statements of the writer make a much deeper and more lasting impression upon the mind of the reader.

The Diary of a Late Physician. By Samuel Warren, D.C.L., F.R.S. Being a New Edition of Selected Passages. Arranged by Charles Wells Moulton. New York, Akron, O., Chicago: The Saalfield Publishing Co., 1905.

This is the sixth volume of "The Doctor's Recreation Series," published under the general editorial supervision of Charles Wells Moulton. "The Diary of a Late Physician" was one of the most popular books of the first half of the last century. It was published first as a serial in *Blackwood's Magazine* in 1830-31, the same periodical in which the author's even more celebrated work, "Ten Thousand a Year," appeared about ten years later. Dr. Warren was born in Wales in 1807 and died nearly thirty years ago at the age of seventy years. He studied both law and medicine, though not practising the latter, and his two chief works have to deal with these two professions. The present work, the full title of which was "Passages from the Diary of a Late Physician," was published in book form, after its completion in *Blackwood's*, both in England and in America, and enjoyed an immense popularity in both countries, running through many editions. The work consists of a number of tales having to do mostly with the tragic side of a physician's life, with the misery and suffering of which he is so often a witness, but powerless to relieve. The stories are rather uneven, though all are powerfully told, and charm by their literary excellence while at times they almost repel by the somber hue and morbidness of the subject. The present edition has been judiciously edited, the stories being shortened by careful pruning of the parts not essential to the tale, while nothing of real interest or necessary to the continuity of the narrative is omitted. The book has been long out of print and its republication in the present collection constitutes a welcome addition to this interesting series intended for the nonscientific shelf of the doctor's library.

Moustiques et Fièvre Jaune. Par A. Chantemesse, Professeur d'Hygiène à la Faculté de Médecine de Paris, et F. Borel, Directeur de la Deuxième Circonscription Sanitaire Maritime. Paris: J. B. Baillière et Fils, 1905.

In this little monograph the authors discuss the sanitary regulations necessary to be enforced, in accordance with the theory of mosquito propagation of yellow fever, to protect Europe from an epidemic of this disease. The normal habitat of *Stegomyia fasciata* being quite distinctly limited by the forty-third parallels of north and south latitude, France is practically outside of the dangerous zone, but Algeria and many of the colonies of France are within the limits of the range of this insect. The subjects treated of are the modern doctrine concerning the spread of yellow fever, history of the disease in Europe, an explanation on the mosquito theory of the epidemics which have occurred at Marseilles, St. Nazaire, Swansea, Oporto, Barcelona, and other places north or south of the forty-third parallel, ship epidemics of yellow fever, etc. The brochure is a not very important addition to the literature of the subject, for it is too large a subject to be treated of satisfactorily in an 18mo book of 96 pages; yet the matter is clearly presented, and the book may be found useful by those who have not the time to study more extensive treatises.

A Text-Book of Diseases of the Chest, Pericardium, Heart, Aorta, Bronchi, Lungs, Mediastinum, and Pleura. By Egbert Guernsey Rankin, A.M., M.D., Professor of Theory and Practice of Medicine, New York Homœopathic Medical College, Physician to the Metropolitan Hospital, Department of Public Charities, and to the Flower Hospital, New York. With 63 illustrations. Philadelphia: Boericke & Tafel, 1905.

The author follows the usual arrangement in a work of this kind, devoting the first section to diseases of the heart, the second to the thoracic aorta, the third to the bronchi, lungs, and pleura, the fourth and fifth to the mediastinum and diaphragm, then a short section on clubbing of the fingers and pulmonary osteoarthropathy, and a final part devoted to the diagnostic and therapeutic uses of the *x*-ray. There are numerous diagrams and plates which are carefully selected and useful. The clinical pictures of the diseases are well drawn and show evidence of experience and a knowledge of the literature. The book being intended for the use of homeopathic practitioners, the treatment recommended includes that of the regular and homeopathic schools, with their appropriate drugs and doses. The text is well written and clear throughout, and the volume is well printed and neatly bound.

Dietetics for Nurses. By Julius Friedenwald, M.D., Clinical Professor of Diseases of the Stomach in the College of Physicians and Surgeons, Baltimore; and John Ruhräh, M.D., Clinical Professor of Diseases of Children in the College of Physicians and Surgeons, Baltimore. Philadelphia and London: W. B. Saunders & Co., 1905.

This little book gives the essentials of dietetics. After an introductory chapter on the Chemistry and Physiology of Digestion, the authors discuss the different classes of foods and the various factors that have a bearing on diet. The feeding of Infants and Children, in health and also in disease, takes up two chapters. This is followed by a short chapter on Diet for the Aged. Rectal Feeding is thoroughly discussed; and general rules are given for the feeding of the sick. The greater part of the book treats of the diet in the different forms and classes of disease, including the infectious diseases, diseases of the stomach, intestines, liver, respiratory organs, circulatory system, genitourinary system, and nervous system. There is also a valuable chapter on the dietetic management of surgical cases. The book is well and pleasantly written and, though designed primarily for nurses, will be a welcome addition to the library of the busy physician. It is not an encyclopedia, but a handy compendium of information on a subject which is of prime importance in the treatment of disease. The authors have shown skill both in the selection of their material and also in the manner in which they have presented it.

# Society Reports.

## THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY.

*Eleventh Annual Meeting, Held in Boston, Mass., June 5, 6, and 7, 1905.*

(Special report to the MEDICAL RECORD.)

THE PRESIDENT, DR. FREDERIC C. COBB OF BOSTON, IN THE CHAIR.

AN address of welcome was delivered by Dr. Frederick Cheever Shattuck, of the Harvard Medical School, on behalf of the local medical profession, after which the President, Dr. Frederic C. Cobb, delivered his address.

**Presentation of Cases.**—Dr. FRANK B. SPRAGUE of Providence, R. I., exhibited a case of tympanomastoid exenteration, showing healing of cavity by blood-clot, and wound by subcutaneous silk suture.

Dr. O. B. Douglas, of Concord, N. H., showed a case of angioneurotic edema in a man forty-one years old. The swelling had first involved one edge of the tongue, and gradually extended to the other, subsiding on the side first affected as it increased on the opposite side, and usually disappearing in the course of twelve hours. The case was interesting, Dr. Douglas said, on account of the possible occurrence of edema of the glottis during one of these attacks.

**Obstruction of the Eustachian Tube a Factor in Post-Operative Mastoid Fistula, and in Chronic Suppuration of the Middle Ear.**—Dr. THOMAS HUBBARD of Toledo, Ohio, read a paper on this subject, in which he offered the following conclusions: Obstruction of the Eustachian tube was a common sequence of acute purulent otitis media and purulent mastoiditis. It was a factor in causing chronic otorrhea, and post-operative mastoid fistulæ. Permanent occlusion gave one indication for the radical operation in chronic purulent otitis.

Dr. EDWARD B. DENCH of New York emphasized the absolute uselessness of depending on drainage through the Eustachian tube, and said that in any case where the otologist had to deal with a foul, persistent discharge resulting from the presence of dead bone, there was only one thing to do, and that was to remove the cause of the suppuration by surgical intervention.

**Carcinoma of the Larynx.**—Dr. S. E. SOLLY of Colorado Springs reported this case. The patient was a woman, 43 years old, who came under observation in September, 1904. Two years before that date she had first complained of hoarseness, which gradually became more severe until her voice was completely lost. Three months ago she had begun to suffer from gradually increasing dyspnea. Inspection of the larynx showed a nodular tumor growing from the anterior wall, and involving about two-thirds of its circumference. Upon microscopical examination of a section of the growth it was demonstrated to be carcinoma. A tracheotomy became necessary to relieve the dyspnea, and subsequently Dr. W. W. Keen of Philadelphia did a total laryngectomy. About a month later some enlargement was observed over the right lobe of the thyroid. The patient refused further operative interference, and died about two months after the operation, the direct cause of her death being obscure, even after a thorough post-mortem investigation. One theory advanced was that the direct cause of death was a lack of parathyroid secretion, one of the parathyroids having been removed at the operation, while the remaining three were involved in the recurrent carcinoma.

Dr. CHEVALIER JACKSON of Pittsburg, Pa., thought it was a good idea to have these patients sit up as early as possible after the operation, as many of the pulmonary complications were the result of keeping them in bed too long, especially if supine. He regarded a preliminary tracheotomy unnecessary. Nutrient enemata he looked upon as a delusion and a snare, and he did not believe they were of any value as a means of prolonging life.

Dr. JOHN F. WOODWARD of Norfolk, Va., reported a case of carcinoma of the larynx and thyroid in which eventually the pneumogastric nerve showed evidences of involvement by pressure, and the patient died by being drowned in his own secretions. The speaker doubted the value of late operations in these cases, inasmuch as tracheotomy seemed to promise most in the way of comfort and prolongation of life.

Dr. E. FLETCHER INGALS of Chicago said the rule should not be lost sight of that laryngectomy should not be done in extrinsic cases; that was to say, when the disease had extended outward beyond the walls of the larynx. In intrinsic cases the results were often very favorable.

**Killian's Inspection of the Trachea and Esophagus.**—Dr. H. P. MOSHER of Boston demonstrated this on the dead subject. Instead of attempting the operation with the patient in a sitting position, as was usually done, Dr. Mosher said that a much better view of the parts could be obtained by placing the patient on his back, with the head hanging down over the edge of the table. If Killian's method failed after a short trial, he advised doing a tracheotomy and then inserting a pair of bent forceps and seizing the foreign body under the guidance of a Kelly cystoscope.

**Symposium.—Intracranial Complications of Middle Ear Suppuration.**

(1) **Meningitis: Its Symptomatology, Diagnosis, and Treatment, with Report of a Case.**—Dr. S. MACCUEN SMITH of Philadelphia said that meningitis from aural disease differed from that due to other causes chiefly in that the symptoms were more severe, and might be relieved by operation. Pachymeningitis externa purulenta was the most common variety. It occurred twice as frequently with chronic disease of the tympanum as it did with the acute form. Localizing symptoms were rare. The most common mode of extension was either through the inner wall of the mastoid, or through the roof of the antrum or tympanum. Leptomeningitis often occurred with sinus phlebitis, brain abscess, or pachymeningitis, but it was usually complicated only by encephalitis. Meningitis manifested itself in a protean manner. Occasionally the symptoms were so typical that it was impossible to mistake the affection; at other times they developed in such a latent form that only with the greatest difficulty could a tentative diagnosis be made. The general symptoms which might precede or accompany the focal symptoms were headache, fever, vomiting, slow pulse, respiratory disturbances, jactication, epileptiform convulsions, general hyperesthesia, delirium, involuntary discharge of urine and feces, and phenomena which were almost focal, such as tetany, grinding of the teeth, rigidity of the extremities, and retraction of the muscles of the neck. Headache was the most common symptom. The focal symptoms related to paralysis of the cerebral nerves, and the symptoms naturally varied according to the principal situation of the meningitic inflammation. The convex portion of the brain was generally affected by suppurative disease, while basilar meningitis was more likely to be of a tubercular nature. As to the treatment, apart from employing general methods, such as the use of rest and the application of cold, very little could be accomplished. If there was reason to suspect disease of the ear, surgical interference was naturally indicated. A recent addition to our therapeutic resources was the operation of lumbar puncture. According to Quincke, the inventor of the method, the operation was indicated in the following conditions: 1. In cerebral pressure, with threatening symptoms, where it was desirable to relieve the pressure. 2. In moderate, long-continued pressure. 3. In conditions in which increased pressure was assumed or suspected. 4. In cases in which it was desirable to examine the cerebrospinal fluid, independent of the cerebral pressure, and thus obtain an opinion as to the nature of the meningitis. 5. In cases in which the fluid was to be examined for diagnostic purposes (blood, toxins, agglutinins, etc.). 6. For the purpose of injecting fluids into the spinal canal as therapeutic agents.

(2) **Symptomatology, Diagnosis, and Treatment of Encephalitis and Brain Abscess.**—Dr. Frederick L. Jack of Boston, Mass., discussed this phase of the subject. He stated that the term encephalitis seemed to have several distinct meanings. In the first place, there was the so-called polioencephalitis, superior and inferior, in which the cranial nerve nuclei of the pons and medulla, respectively, were destroyed either suddenly (acute polioencephalitis), or gradually (subacute and chronic polioencephalitis). In the second place, there was the acute exudative form (hemorrhagic encephalitis), described by Dana as following influenza, cerebrospinal meningitis, typhoid fever and other infectious diseases. This apparently never resulted in suppuration. Thirdly, and of special interest to otologists, came the acute suppurative encephalitis, a term synonymous with cerebral abscess. This form of encephalitis was the result of extension from the ear cavities of pyogenic microorganisms, either directly, or along the blood vessels, and together with meningitis, which was the diffuse result of a similar infection, it furnished the principal cause of a fatal outcome in the cases with which the otologist had to deal.

(3) **Symptomatology, Diagnosis, and Treatment of Sigmoid Sinus Thrombosis.**—By Dr. James F. McKernon of New York. In the symptomatology of the typical cases the speaker said he considered temperature by far the most important feature. Chills were present in only a certain proportion of the cases seen. In most of the cases of thrombosis coming under his notice the degree of pain was greater than that complained of with an ordinary mastoiditis or that following the average post-operative case. The pain was usually referred to the side of the head and to the occipital region, and very frequently was localized in the region of the torcular. Nausea and vomiting were usually present at some stage of the disease, to a greater or lesser degree. Vertigo was observed only when the meninges were involved. Cerebration had been normal excepting in advanced cases. Among the local symptoms, edema in the mastoid region and over and around the exit of the emissary and occipital veins was occasionally observed. The so-called Gerhardt symptoms he had never seen demonstrated. In a fair proportion of the adult cases there was a marked stiffness of the muscles of the neck on the affected side, and in several instances a marked rigidity. Constipation was present in all his cases, but only in the earlier stages of the disease. Among the general symptoms at the outset might be mentioned malaise, loss of appetite, a dry and heavily furred tongue, and a foul breath. The face usually wore an anxious and pallid look, the skin was dry and later presented the yellowish tinge indicative of sepsis. The hard cord-like swelling in the neck along the course of the internal jugular vein was a very infrequent sign, and the speaker said he had never been able to demonstrate it. Bacteriological examination of the discharge was of value only in that it gave the character of the infection. Another valuable aid in the diagnosis was the blood-count, not so much for determining whether a leucocytosis was present, but to ascertain the polynuclear percentage.

(4) **Pathological Findings of Intracranial Complications of Middle Ear Diseases.**—Dr. Thomas J. Harris of New York read this paper, in which he called attention to the lack of material relating to this phase of the subject upon which to base reliable conclusions, and he emphasized the importance of greater attention on the part of the surgeon in charge to the taking and preservation of the histories of his mastoid cases.

Dr. Edward B. Dench of New York opened the discussion on this subject, and gave the following personal statistics: He had observed twelve cases of brain abscess (9 temporosphenoidal, 3 cerebellar); 38 cases of sinus thrombosis, in 13 of which the internal jugular was excised; 28 cases of epidural abscess, and 4 cases of meningitis. These statistics were fairly accurate, excepting those for meningitis. Under that heading many cases escaped observation, as only those operated upon had been recorded. From these statistics it appeared that the relative frequency of the various intracranial lesions had been as follows: Epidural abscess, 34.1 per cent.; brain abscess, 14.6 per cent.; sinus thrombosis, 46.3 per cent.; general meningitis, 4.8 per cent. Of the sinus thrombosis cases, the jugular was tied in 36.8 per cent. Regarding the mortality of the various conditions, of the 12 cases of brain abscess 3 were cured and 9 died; of the 38 cases of sinus thrombosis, 32 were cured and 6 died. In 25 cases the internal jugular was not excised, and of these 22 were cured and 3 died. In 13 cases the jugular was excised, and of these 10 recovered and 3 died. Of the 4 cases of meningitis operated on, 1 was cured and 3 died. From these statistics it appeared that the two classes of cases that were attended by the highest mortality were brain abscess and diffuse meningitis, either of the purulent or serious variety. Epidural abscess and sinus thrombosis, including those cases where the jugular demanded excision, need not be looked upon as being of such a very serious character if the cases were operated upon early.

Dr. Wendell C. Phillips of New York said statistics showed that injuries to the head were quite frequently associated with attacks of meningitis from middle ear suppuration. Such a sequence was not difficult to understand. The only barrier between the suppurative process in the ear and the brain was a rather thin plate of bone, and it was quite probable that a severe injury to the head might be the actual exciting cause of the intracranial complication. The fact could not be too strongly emphasized that serious intracranial complications were more frequently observed in connection with chronic than with acute middle ear disease.

Dr. Charles W. Richardson of Washington, D. C., said that in the treatment of the radical mastoid wound he did not look with favor upon the application of skin-grafts to the freshly exposed dura, as this was apt to give rise to the development of granulation tissue, and cause unpleasant symptoms. He was also opposed to the treatment of the wound by the formation of a blood-clot, as that was another method by which infection could be readily carried into the cranial cavity.

**Tinnitus Aurium and Hallucinations of Hearing; or, Relation of Ear Disease to Auditory Hallucination of the Insane.**—Dr. W. Sohier Bryant of New York read a paper on this subject. He stated that hallucinations of hearing were much more common and of greater psychological importance than other hallucinations, and that they were usually the primary ones. In the order of their importance, hallucinations were classified as hallucinations of hearing, of sight, of smell, and of touch. There was considerable evidence showing the association of ear disease with auditory hallucinations. The results given by a number of observers showed that in the majority of cases the patients were also suffering from ear disease. In many of the hallucination cases, tinnitus was also complained of; in fact, very few of the cases were free from disturbed aural function of the kinds which were usually accompanied by tinnitus. Without exception, unilateral auditory hallucinations occurred on the same side as the ear lesions. There was therefore good evidence that auditory hallucinations were often dependent on ear disease, and that some of the cases were due to stimulation of the auditory centers by peripheral tinnitus aurium. The gravity of the pathological impressions depended chiefly on the degree of psychical instability; they varied from mere conscious illusions to hallucinations under the patient's control, and from hallucinations to dominant delusions.

**Frontal Sinusitis; Diagnosis, Treatment, and Results.**—Dr. C. G. Coakley of New York in this opening paper of a symposium on "Diseases of the Accessory Sinuses," said the indications for the external operation upon the frontal sinus were: 1. Chronic suppurative frontal sinusitis, associated with multiple polyp formation in the nose. These cases were always combined with an ethmoiditis. 2. In

severe acute exacerbations of the chronic disease. 3. If intranasal treatment of the frontal sinus did not suffice to prevent the discharge from passing to the antrum, and the odor and taste of the fetid discharge from the latter cavity annoyed the patient. 4. Very large frontal sinuses, with multiple septa, particularly those with recesses extending back over the roof of the orbit, could be but imperfectly irrigated. 5. Patients with narrow nasal cavities offered great difficulty in carrying out the intranasal treatment. 6. Patients who desired a rapid and permanent cure, neurasthenic patients, and cases into which a fistula leading into a frontal sinus had formed. Dr. Coakley said he had performed the Ogston-Luc operation twenty-five times, and in fully one-half of these there had been a recurrence of the sinusitis, as well as of nasal polypi. The deformity resulting from this operation was practically only a linear scar, which after a few months was scarcely visible. The objection to the operation was the great number of recurrences, owing to the fact that the mucous membrane in the frontal sinus was not removed. Dr. Coakley then described in detail the so-called "open method," which consisted in removing the entire anterior wall of the frontal sinus, thorough removal of the mucous membrane from all parts of the cavity, and the exposure and removal of the mucous membrane from the ethmoidal cells surrounding the nasofrontal duct. Granulations were then allowed to fill the lower portion of the nasofrontal duct, and the upper portion was packed with gauze until the cavity was completely obliterated. The speaker said his results with the "open method" had been so satisfactory that he had not as yet attempted the Killian operation. From May 16, 1901, to January 1, 1905, he had performed the "open method" operation on 104 patients; of these, nine had a double frontal sinusitis. Of the 104 patients, 101 had their frontal sinuses obliterated as a result of a single operation. One patient, with double frontal sinusitis, operated on over two years ago, still had a fistula, with slight secretion. Two patients had each been operated on twice. Two were dead—one from chloroform narcosis, the other from pneumonia.

**The Intranasal Route in Operating Upon the Nasal Accessory Sinuses.**—Dr. Walter A. Wells of Washington, D. C., discussed this phase of the subject. The objections that had been raised against employing the nasal route in the treatment of the accessory sinuses might be summarized as follows: 1. That it was not always practicable. 2. That valuable time was lost in postponing radical measures. 3. That the nasal methods were generally slow and tedious. 4. That they were uncertain as to results. After answering these objections, and emphasizing the importance of limiting the conservative methods to properly selected cases, the author discussed at length the various methods that had been devised to treat the nasal accessory sinuses through the nose. The nasal route to the antrum of Highmore included: 1. Irrigation through the natural opening. 2. Irrigation through an artificial puncture with trocar in either the middle or inferior meatus. 3. A large opening in the outer wall of the nose. In disease of the ethmoid cells, most authors were agreed as to the advisability of attempting a cure by operation through the nose when there was but a mild state of inflammation present, or when the disease was circumscribed and limited to but a few cells. The advantages of the nasal route, when feasible, was that it opened the cells at their most dependent situation, it was attended with a minimum of surgical intervention, and it avoided disfiguring external scars. The external operation upon the frontal sinus, especially when it aimed at a complete obliteration of the sinus, was sometimes attended with such a hideous deformity that the patients frequently decided to refuse to consent to it. Three methods had been used of approaching the frontal sinus by way of the nose: 1. Simple irrigation through the natural opening. 2. Drilling through the anterior superior wall. 3. Enlarging the nasofrontal canal. Among the methods devised for attacking the sphenoidal sinus, Dr. Wells mentioned and described the frontoethmoidal, the orbitoethmoidal, the maxillary, the intranasal, the nasopharyngeal, and the various operations of Rouge, Oelier, Moure, Jansen, and others. The intranasal route commended itself as being the most direct and conservative; it avoided deforming cicatrices and the exposure of other healthy sinuses to possible infection.

**Further Experience with Radical Operations for Frontal Sinus Disease.**—Dr. Wolff Freudenthal of New York said that since his last report on the radical operation for empyema of the frontal sinus a year ago he had operated on four additional cases. As to the indications for a radical operation in dealing with that condition, there were still strong differences of opinion, and extremists were found on either side. While some operated far too often, we were not justified in saying, as some did, that in former years, when radical operations were unknown, frontal sinus disease was treated without fatal results. The main question to decide was, could we by operating save a given case which would otherwise be doomed? The answer to this was yes, because we were now able to make a diagnosis of frontal sinus affections more readily than we could ten years ago. In some instances, the possibility of meningeal infection was invited by postponing surgical intervention. On the other hand, there were thousands of cases of chronic empyema of one or more of the accessory sinuses for the relief of which a radical operation was unnecessary. The fact should not be lost sight of that these radical operations were always dangerous, and had resulted in many serious and even fatal accidents. Still, there were cases in which such an operation was absolutely imperative.

**Results of Operations by Way of the Maxillary Route for Combined Disease of the Maxillary Antrum, the Ethmoid Labyrinth, and the Sphenoidal Sinus.**—Dr. T. Passmore Berens of New York described this operation as follows: A postnasal tampon was first inserted, and the tongue held forward by a ligature passed through its tip. An opening was then made into the antrum through the canine fossa, and enlarged until the anterior lateral wall was almost completely removed. The bony nasoantral wall was then entirely removed, the mucous membrane on its nasal side being as far as possible preserved. The ethmoid cells and the turbinate process of the ethmoid were then removed. The sphenoid was opened, either through its ostium or through the posterior ethmoid cell: this opening was then enlarged until as much as possible of the anterior wall had been removed, and the cavity of the sphenoid was examined and its diseased contents removed. The field of operation was illuminated by means of a headlight worn by the operator. Instrumentation was further aided by the insertion deeply into the nostril of the little finger. This combination of the sense of sight with the sense of touch did much toward removing the feeling of uncertainty with which operations on the deeper structures of the nose were usually approached, and was a strong recommendation for the selection of this rather than the intranasal route. Bleeding during the operation was usually controlled by gauze tampons dipped in adrenalin solution, although a resort to artery forceps to catch the spheno-palatine vessels was occasionally necessary. Dr. Berens emphasized the fact that this operation was designed especially for the relief and cure of those cases of chronic multiple sinusitis involving the antrum and ethmoid, or antrum, ethmoid, and sphenoid, and was not meant to be commonly performed for disease limited to the ethmoid or sphenoid, or for mild or ordinarily acute conditions.

**The External Operation for the Relief of Ethmoiditis.**—Dr. Lewis A. Coffin of New York said his preference for the external operation over the intranasal operation was based on the following reasons: 1. By the intranasal method the middle turbinate had to be sacrificed. 2. The intranasal operation was long drawn out and painful. 3. There were certain parts of the ethmoidal tract that could not be reached by the intranasal method.

**New Operation and Instruments for Draining the Frontal Sinus.**—Dr. E. Fletcher Ingals of Chicago described an operation which consisted, in brief, of passing a steel pilot through the natural canal into the frontal sinus, and running in over this a hollow burr, by which a canal six mm. in diameter was made, and then inserting into this canal a self-retaining gold tube so large that the pus would necessarily drain, and that the patient might easily wash out the sinus. The advantages of this operation were the following: 1. It caused no scar, afforded efficient drainage, and enabled the patient himself to easily cleanse the sinus. 2. It was much safer than any other intranasal method. 3. It could be done early, before permanent pathological changes had taken place, and in such cases it might be expected to effect a cure. 4. The early establishment of free drainage usually prevented serious pathological changes. 5. It was no bar to a later external operation, if that should become necessary; indeed, it rendered the external operation less formidable. 6. It would cure a large percentage of the chronic cases.

**Two Successful Cases of Obliteration of the Frontal Sinus After Repeated Operations.**—Dr. H. Holbrook Curtis of New York reported two cases of long-standing frontal sinus disease that were successfully treated by the open method.

Dr. George L. Richards of Fall River, Mass., showed three cases of double and one case of unilateral frontal sinus disease successfully treated by the obliteration method. He also exhibited a number of anatomical specimens showing abnormal conditions of the accessory sinuses.

Dr. Joseph Payson Clark of Boston spoke of the deformity that often resulted from the radical operation for frontal sinus disease. He favored improvements in the Ogston-Luc method, which showed fifty or more per cent. of cures. He urged that each case be carefully studied, and the most conservative treatment adopted that seemed applicable to the case in question.

Dr. Lee M. Hurd of New York said he had done conservative work in fifteen cases of frontal sinus disease, and had secured perfect drainage.

Dr. Thomas J. Harris of New York said the most important feature in any method of operation on the frontal sinus was to secure free drainage. He thought there was room for an operation that would give rise to less deformity than that practised by Dr. Coakley, and called attention to the fact that the radical operation was not unattended with risk to life. The majority of these patients would be benefited by and satisfied with conservative methods of treatment.

Dr. H. P. Mosher of Boston showed two patients who had been operated on by the open method, and said that the more he studied the anatomy of the frontal sinus in the dissecting-room, the more he felt like getting a view into the sinus in the cases he had to deal with clinically. He even favored opening the sinus for exploratory purposes.

**Report of a Case of Inflamed Dentigerous Cyst Simulating Abscess of the Antrum of Highmore, Caused by an Odontoma.**—Dr. William H. Haskin of New York reported this case, and showed the specimen.

**A Case of Infective Thrombosis of the Sigmoid and Lateral Sinuses After Acute Mastoiditis; Death from Meningitis; Autopsy Report.**—Dr. Arnold Knapp of New York reported this case.

**An Unusual Case of Laryngeal Syphilis, Requiring Tracheotomy.**—Dr. Clement F. Theisen of Albany, N. Y., reported this case.

**Nose and Ear Complications in Diphtheria, Scarlatina, and Measles.**—Dr. John H. McCollom of Boston, in this paper, emphasized the following points: 1. The frequency of otitis media in diphtheria, scarlet fever, and measles. 2. The importance of early operation in mastoiditis occurring in these diseases. 3. The necessity of frequent examination of the ears, even when there were no symptoms referable to those organs. 4. Early incision of the drumhead in the acute infectious diseases, as soon as there was any bulging. Dr. McCollom also suggested that if adenoids were to be removed, cultures should be taken from the nostril in every case before the operation was done, as it frequently happened that a child who had a profuse discharge from the nose, immediately after the removal of the adenoids, or after ablation of the tonsils, developed a severe attack of diphtheria.

Dr. Thomas Hubbard of Toledo, Ohio, thought the suggestion made by Dr. McCollom to have the nasal secretions examined bacteriologically before operating on the tonsils or adenoids was a very important one; it was a well-known fact that cases of latent or very mild nasal diphtheria were comparatively frequent, and in fibrinous rhinitis it was impossible to determine positively the character of the infection without a bacteriological examination. These mild cases were a prolific source in spreading the disease among children.

Dr. George A. Leland of Boston said that in the management of aural complications during the acute exanthemata he strenuously insisted on not delaying examination for the secondary rise of temperature. The ears should be examined as a matter of routine from the onset of the disease.

Dr. McCollom, in reply to a question, said he would not hesitate to advise operating on the mastoid, even in the height of an attack of one of the exanthemata. The danger of postponing the operation was greater than that entailed by the operation itself.

**Scarlatinal Otitis.**—Dr. Frank B. Sprague of Providence, R. I., said that otitis media was the most frequent complication of scarlet fever, and, everything considered, the most serious. Like the general infection, its severity varied with the epidemic, the climate and the seasons of the year. It was more common in the winter and spring months, and in the colder climates. Statistics showed that from three to nine per cent. of the cases of scarlet fever had ear complications, and in about fifty per cent. of these cases both ears were affected. Statistics further showed that of 5,613 deaf mutes in New York, 572, or nearly ten per cent., owed their condition to otitis complicating scarlet fever. In view of the serious consequences of this condition, Dr. Sprague emphasized the importance of its early recognition. We should not expect and wait for the ear to "break and run," as was so often done, for this was but little short of criminal negligence. As soon as there was the slightest indication of inflammation in the middle ear, the tympanic membrane should be incised, so as to preserve, if possible, the function of one of the most important organs of special sense.

**The Indications for Operating in Acute Mastoiditis.**—Dr. Philip D. Kerrison of New York said the indications for operating in acute mastoiditis might be summed up as follows: 1. Sudden cessation of the aural discharge, other symptoms persisting; deep-seated pain in the mastoid region; marked sensitiveness to pressure upon the mastoid over an area extending well beyond the limits of the antrum. These symptoms, in the presence of a sudden and considerable rise in temperature, would justify an immediate operation. 2. In the absence of fever, the above symptoms, unless yielding promptly (within twenty-four to forty-eight hours) to abortive measures, would constitute a sufficient reason for operating upon the mastoid. 3. Marked tenderness over the antrum, persisting four or five days after free incision of Shrapnel's membrane would point to necrotic changes within the antrum calling for operative intervention. 4. Marked variations in the quantity of pus discharged, its maximum flow being apparently too great to be explained by the tympanic lesion, its periods of diminution being coincident with the development of mastoid pain or tenderness, or both. Such a combination of symptoms constituted one of the most positive indications for opening the mastoid. 5. Mastoid tenderness having been present and having disappeared, a discharge from the

tympanic vault which resisted all rational non-operative measures might, by reason of its persistence, justify the hypothesis of a necrotic area in the aditus or antrum. In such cases an operation was often the only means of saving the integrity of the organ and preventing serious impairment of function. 6. Evidences of mastoid involvement having been present, the development at any time during convalescence of symptoms of septic absorption would, in the absence of other concurrent disease, constitute a positive indication for immediate operation.

**The Larynx in Typhoid Fever.**—Dr. Chevalier Jackson of Pittsburg, Pa., gave a brief résumé of his observations of the larynx made in 360 cases of typhoid fever. Three separate types of laryngeal involvement were noted, namely, acute catarrhal laryngitis, ulcerative laryngitis, and perichondritis. Among the 360 cases examined, ulcerative laryngitis was observed in 68, of which 8 required tracheotomy; there was perichondritis, with necrosis, in 6, and without necrosis in 11; there was ulcerative trachitis in 9. Eleven were associated with acute purulent otitis media. Four died. The most important factor in the etiology of the condition was the typhoid toxemia. As regarded treatment, intubation was useless and dangerous, but tracheotomy, if done early, was a life-saving measure. Ulceration in even the worst cases healed in ten days after tracheotomy and treatment through the tracheal wound. Tracheotomy should be done under local (Schleich solution) anesthesia.

**Acute Purulent Otitis Media Complicating Typhoid Fever: Report of a Case, with Autopsy.**—Dr. Ewing W. Day of Pittsburg, Pa., reported this case, in which the autopsy findings indicated that the otitis media was due to embolism or thrombosis of the tympanic and mastoid blood vessels.

**Report of Seven Intracranial Operations Within a Year.**—Dr. George F. Cott of Buffalo, N. Y., read a paper with this title.

The following papers were also read and discussed: "The Serum Treatment of Hay Fever," by Dr. Hanau W. Loeb of St. Louis, Mo.; "Syphilis of the Nose and Accessory Sinuses," by Dr. James E. Logan of Kansas City, Mo.; "Syphilitic Manifestations in the Larynx and Trachea," by Dr. Francis B. Packard of Philadelphia; "Report of a Case of Abscess in the Temporosphenoidal Lobe of the Brain Following an Acute Otitis Media; Operation; Recovery," by Dr. Thomas H. Halstead of Syracuse, N. Y.; "Orbital and Meningeal Infection from the Ethmoid Cells; Report of a Case; Death," by Dr. James F. McCaw of Watertown, N. Y.; "The Significance of Edema of the Pharynx," by Dr. Jacob E. Schadle of St. Paul, Minn.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, May 18, 1905.*

The President, Dr. Charles L. Dana, in the Chair.

**Presentation of Portrait of Andrew H. Smith, M.D.**—By Dr. George L. Peabody. (See page 182.)

**The Medical Examination of Immigrants, and What the Nation Is Doing to Debar Aliens Afflicted with Trachoma.**—Dr. George W. Stoner, of the Marine Hospital Service, Ellis Island, presented a paper on this subject, which, in Dr. Stoner's absence, was read by Dr. John McMullen. The author stated that New York was the gateway of about 75 per cent. of the total immigration into the United States. More than 600,000 aliens arrived at this port during the fiscal year ended June 30, 1904, nearly three times as many as at all other ports of the country combined. Eighteen per cent. were cabin passengers, and 82 per cent. came in the steerage. In addition to the 600,000 aliens, more than 100,000 cabin and steerage passengers arrived, who, after primary inspection, proved to be citizens of the United States. Dr. Stoner then described in detail the work of the medical officers at Ellis Island, and quoted the regulations governing the service under which immigrants might be excluded. This included all idiots, insane persons, epileptics, persons who had been insane within five years previous, persons who had had two or more attacks of insanity at any time previously, and persons afflicted with a loathsome or a dangerous contagious disease. Of these, trachoma was one of the most troublesome, and the eyelids of all arriving immigrants were everted and carefully examined. Trachoma was classified by the Government as a dangerous contagious disease, and all aliens suffering from it were excluded. All cases of chronic trachoma had not been placed in that category, for the reason that in some cases it was difficult to say that the disease was not quiescent or apparently cured at the time of foreign embarkation, and a competent medical examiner might have been honest in his opinion that the disease was cured. Among the thousands of arriving aliens at this port, all forms of inflammatory diseases of the eye were met with, from the simplest conjunctivitis to the most severe form of trachoma. The mild cases of conjunctivitis were not detained; others, somewhat more marked, were admitted to the hospital for further observation. Some cases of acute, follicular, or slightly granular forms of conjunctivitis were held for a further period of observation or treatment—a fortnight or longer, if necessary. In excluding persons suffering from trachoma, the object was not only to prevent the introduction into this country of a communicable disease, but also to keep out a class of immigrants from whom so large a proportion of the inmates of institutions for the blind, and recipients of public dispensary charity were recruited. Last year, according to the report of the Commissioner-General, 7,994 aliens were excluded at the seaports of the United States, including 1,560 afflicted with a loathsome or dangerous contagious disease, and 787 of these were excluded at the port of New York on account of trachoma. It was not until 1897 that trachoma was classified by the Government as a dangerous contagious disease.

**What Proportion of Blindness (and Defective Vision) in the State Is Due to Ophthalmia of the New-Born?**—Dr. Lucien Howe of Buffalo discussed this phase of the subject, and exhibited a number of charts and diagrams showing the relative proportion of blindness in different sections of the United States. He called attention to the fact that blindness was more common, proportionately, in sparsely settled sections than in the centers of population, and this he attributed to the more prompt and efficient medical service obtainable in the cities. To show the comparative value of the preventive treatment of ophthalmia of the new-born, Dr. Howe gave the following figures: Of 17,767 cases with no treatment, 9.2 per cent. became blind; of 24,724 treated with a two per cent. solution of silver nitrate, 0.65 per cent. became blind; of 1,223 treated with a one per cent. solution of silver nitrate, 2.4 per cent. became blind. While the population of the State had increased from five millions in 1890 to about seven millions in 1900, the number of the totally blind and the partially blind, taken together, had only increased from 4,389 to about 5,486 during the same period. Although these figures were encouraging, they should only serve to stimulate physicians to greater effort. Especially in public institutions it should be made compulsory to apply a solution of silver nitrate or something equally efficacious to the eyes of every new-born child. If this prophylactic measure was universally employed, ophthalmia of the new-born would practically be unknown in civilized communities.

**What Is the City Doing, Through the Regulation of Midwives, or Other Means, to Prevent Ophthalmia of the New-Born?**—Dr. H. W. Wootton discussed this phase of the subject. He stated that in attempting to prevent the more serious consequences of ophthalmia in the new-born, the New York Department of Health had required for some time past that midwives should register their names with the Bureau of Vital Statistics, and that they should report the occurrence of such cases. Upon the receipt of such a report by the Board of Health, an inspector visited the case and impressed upon the family the serious nature of the

disease, and the necessity for prompt and vigorous treatment by an attending physician, by daily visits to a dispensary, or by removal to a hospital. This method of procedure had been productive of considerable good, but as the cases reported had been few in comparison to the number that probably had existed, the Department recently decided that further steps were necessary. Circulars had been prepared, calling the attention of midwives to that Section of the Sanitary Code which required them, under penalty of fine or imprisonment, to promptly report to the Department of Health the occurrence of cases of ophthalmia neonatorum. Circulars similar in nature were also to be sent to physicians and hospitals, which were intended, for the most part, to aid in the detection of midwives who had failed to report their cases. In addition to the above measures, Dr. Wotton said he thought it might be wise on the part of the Department to call the attention of midwives to the preventive method of Credé, and to urge them to employ it.

**What Means Does the Modern Obstetrician Employ to Prevent Ophthalmia of the Newly Born?**—Dr. J. Clifton Edgar said that from the standpoint of the obstetrician there were two means at our command for reducing the frequency of, if not practically preventing, ophthalmia neonatorum. The first was the antepartum preparation of the maternal passages in cases where they were suspected of being infected; the second was to drop into each conjunctival sac immediately after delivery some antiseptic, such as the nitrate or some organic salt of silver. When the maternal passages were suspected, a preliminary course of treatment of the vagina should be instituted, beginning about two weeks before delivery. This should consist in daily or more frequent vaginal douching, first with a mild alkaline solution, and then with one of bichloride of mercury, 1-5,000. Just before delivery, a substitute had to be provided for the normal lubricating mucus which had been washed away by the douching process, and a one per cent. lysol solution would be found useful for that purpose. The scientific dictum of Bumm and Krönig, namely, that the vaginal secretion had a bactericidal action, had been misunderstood as applying to gonococcus infection. It had no such action in those cases. For the prevention of ophthalmia neonatorum, Dr. Edgar said he had every faith in Credé's method, and in both his hospital and private cases he was now accustomed to make use of this method without exception. After repeated experiments with the organic silver salts, he had found that they did not compare with a two per cent. solution of silver nitrate as a prophylactic. As soon as the child was born, its face was carefully washed with boric acid solution, separate pledgets of cotton being used for each eye, and the lids rubbed from the nose outward in each case. Then, whether infection was suspected or not, two drops of a two per cent. nitrate of silver solution were dropped into each conjunctival sac. The excess was washed away in about thirty seconds with a decinormal saline solution. In the speaker's experience, solutions weaker than two per cent. did not destroy bacteria, and while solutions of three per cent. were harmless, they were apt to cause "silver catarrh," and were not required. While antepartum cleansing in suspected cases, and Credé's nitrate of silver method after birth could not absolutely abolish gonorrheal ophthalmia, because of the occurrence of a small percentage of cases in which the infection was intrauterine, those two measures could reduce the morbidity to practically *nil*.

**What Is the Most Approved Treatment of Ophthalmia of the New Born?**—Dr. P. A. Callan said that in comparing the result of treatment of ophthalmia in the newborn with that of the adult, the difference was most striking. The outcome of the disease in the former was eminently satisfactory, while in the latter it left much to be desired. We had every reason to expect a good result in the treatment of the newborn, presupposing that the disease was recognized at an When seen early, ice-cold compresses should be applied. Cold inhibited the rapid development of the germ. After the cornea became involved, hot water compresses, at a temperature of 120° to 130° F., should be used instead of the cold. The eyes should be kept clean and free from pus. This was best accomplished by gently separating the eyelids, and flooding the eyeball with a 2 per cent. solution of borax, or a 4 per cent. solution of boric acid. All rough manipulation of the eye was to be avoided. The safest way to flush out the eye was to use a good-sized pledget of cotton, saturated with the solution. The cotton should not come in contact with the eyeball, but, if necessary, the edges of the lids might be wiped free from the adherent pus. The frequency with which the cleansing should be repeated depended on the amount of pus secreted; in some cases it was necessary every few minutes; in others, less frequently. The attendants should be warned of the danger of infecting their own eyes. All the cotton that came in contact with the eyelids should be burned. The best germicidal agent for this disease was nitrate of silver, in a one to two per cent. solution, applied to the everted eyelids once or twice daily, depending on the severity of the symptoms. The weaker solution could be used twice daily. It was not good practice to drop the solution on the cornea, but rather apply it directly to the swollen conjunctiva with a camel's hair brush, washing off the excess with salt solution. The chief objection to the use of silver nitrate was the pain it gave rise to. There were other silver preparations in use which did good service. The great majority of these patients could be safely looked after at their own homes.

Dr. Charles J. Kipp of Newark, N. J., stated he could add very little to what Dr. Callan had said regarding the treatment of these cases. In the mild cases he used a one per cent., and in the severe cases a two per cent., solution of silver nitrate, which he had found superior to the organic salts of this metal. Most of the cases of ophthalmia of the new-born that came under his observation were seen in private or dispensary practice; rarely in institutions. Many physicians still failed to use the Credé method, and the law compelling midwives to report their cases was usually disregarded.

Dr. Thomas R. Pooley said that while the law debarring the visually-defective immigrant was apparently sufficiently stringent in dealing with cases of trachoma, he thought its provisions should be extended so as to cover other forms of visual defects which could only be discovered by a careful examination of the fundus of the eye. Under this head he included retinitis pigmentosa, different forms of congenital cataract, and atrophy of the optic nerve, or any other visual defect which might permanently interfere with the earning power of the individual. Dr. Pooley said he had always had some doubt about the specific prophylactic treatment of ophthalmia neonatorum. During the earlier stages of labor the infant's eyes were tightly closed, and it was not until the head emerged from the vulva that there was great danger of infection. Careful ablution of the child immediately after birth, with thorough cleansing of the eyes with some aseptic solution, would have all the effects of a one per cent. solution of silver nitrate, without its disadvantages—and a two per cent. solution was still worse. Dr. Pooley said that at a recent meeting of the New York Ophthalmological Society there was a discussion on the relative value of silver nitrate as compared with the organic salts, and the consensus of opinion was that the silver nitrate was superior to the others. In treating a case of ophthalmia neonatorum, the speaker emphasized the fact that the manipulations should be made with the greatest gentleness, so as to preserve the integrity of the cornea.

Dr. Edwin B. Cragin gave the results of his experience with the different salts of silver at the Sloane Maternity during the past six years. During the first two years of that period nitrate of silver had been almost exclusively used as a prophylactic against ophthalmia neonatorum; during the second and third two years solution of two of the organic silver salts had been substituted. In the entire period of six years the sight of one eye was lost, and that

was during the time when one of the organic solutions was being used. There were no other bad effects from the use of these solutions, except in one instance, when a small ulcer of the cornea resulted.

Dr. Emil Gruening said he had recently paid a visit to Ellis Island, and could corroborate what had been said regarding the thoroughness of the medical officers there in excluding immigrants who were suffering from trachoma. In regard to debarring immigrants who were suffering from optic nerve atrophy, retinitis pigmentosa, etc., to which Dr. Pooley had referred, the distinction should not be lost sight of that those diseases could not be regarded as a menace to others, while trachoma was.

Dr. Richard H. Derby emphasized the importance of more strictly enforcing the law compelling midwives to report cases of ophthalmia neonatorum.

Dr. Alexander Duane thought that cases of ophthalmia of the new-born were best treated at home, in spite of poor hygienic surroundings. In the hospital they were usually subjected to a certain amount of over-treatment, particularly in the matter of cleansing the eye. The speaker cautioned against the forcible douching of the eye, and favored the use of moist pledgets of cotton, first wiping the exterior of the lids, and removing the discharge very carefully before applying the silver solution. He did not think cold applications subserved any useful purpose after the edema of the lids began to subside. He withdrew them as soon as there was any evidence of involvement of the cornea, and substituted hot applications. In cases that went on to intractable disease of the cornea, the patients were usually poorly nourished, and proper dietetic and hygienic measures should not be lost sight of.

Dr. J. Herbert Claiborne said he agreed with Dr. Pooley in regard to the importance of deporting immigrants who were visually defective. In addition to the class of cases mentioned by Dr. Pooley, which were quite as important as trachoma, he would also debar persons with a very high grade of myopia and extensive choroidal changes. In the treatment of ophthalmia neonatorum, Dr. Claiborne said he thought that silver nitrate solution was a much more valuable remedy than any of the organic salts. He had the greatest faith in Credé's method as a prophylactic measure, and any one who reviewed the statistics on the subject would surely be convinced of its value.

---

SECTION ON SURGERY.

*Stated Meeting, Held May 5, 1905.*

Dr. Samuel Floyd in the Chair.

**Epithelioma of Lip.**—Dr. C. Am Ende presented this case. The patient had suffered from a tumor, which gave many clinical evidences of malignancy.

**Metastatic Tumor of Breast.**—Dr. Am Ende also presented this case. It occurred in a young woman. Each of these patients had been much benefited by the use of the author's method of treating cancer.

**Carcinoma of the Male Breast Cured by the Röntgen Ray.**—Dr. Sinclair Tousey presented this patient. The tumor had been typical of a benign condition in the very act of becoming malignant. The result was a perfect one.

**Fibroma of Sheath of Tendon.**—Dr. Franz Torek presented this patient. He said that he had been able to find but one case of fibroma originating in the tendon sheath. This case had been reported many years ago. Dr. Torek's case occurred in a young woman, and the result, although good, had left the finger somewhat enlarged.

**A Case Showing Author's Radical Operation for Carcinoma of the Bladder.**—Dr. Albert A. Berg presented this case.

**Volvulus of the Entire Omentum.**—Dr. Charles A. Elsberg presented this specimen. He said that the patient had been sent to the hospital with a diagnosis of acute appendicitis, and called attention to the distinguishing characteristics which are conceded to exist between the two.

**Operation for Congenital Goiter.**—Dr. E. W. Peterson presented this patient. The lesion had occurred in a baby, but operation had been deferred until the growth had become of such extent as to involve the trachea and cause considerable dyspnea. It was located in the extreme right side of the neck and was, therefore, naturally mistaken in its nature. After the entire removal of the growth, it was found to be a congenitally misplaced thyroid. The little child was profoundly sick after the operation, having pronounced dyspnea, temperature of 105.5°, convulsions, twitching of the extremities, and other manifestations of profound disturbance. Clinically the symptoms were of a definitely tetanoid character.

Dr. Peterson also reported a case of operation for large cystic goiter.

**Treatment of Cancer by Thyroid Gland Extract Combined with the X-Ray.**—Dr. C. Am Ende read this paper. He said that the majority of the cases reported were unfinished and as yet under treatment. He dwelt upon the fact that success in the use of these extracts depended entirely upon the utilization of absolutely pure material. He said that they might be administered either in substance, by capsules, or in a liquid form as the fluid extract. To this he recommended the addition of one per cent. of aromatic tincture. The individual susceptibility of patients to thyroid extract was well known, but he had found that the dose varied from four to six grammes a day. It was possible in certain instances to increase this to twelve grammes. Not all patients could be expected to respond equally to the treatment. Except in recurrent uterine carcinomata larger doses proved the best to begin with. The speaker referred to the curious fact that after the failure of either thyroid extract or the *x*-ray, occasionally their combined use had resulted favorably.

Dr. Aspinwall Judd said that out of twelve cases, nine had been improved and three cured. He stated that those epitheliomata which had an usual number of cell nests represented a class of tumors which had always proved most resisting to the *x*-rays. These growths were, in the speaker's opinion, particularly suited for treatment by the combined method. He said that primary carcinomata did not respond to the *x*-ray, whereas, as was well known, secondary carcinomata were almost always favorably affected.

**Advantages of Iodine Catgut and the Modification of Its Preparation.**—Dr. A. V. Moschowitz read this paper. It was a contribution from the pathological laboratory of the Columbia University, as well as a clinical report from the wards of the Mt. Sinai Hospital. The author presented a series of photographs which showed the results of his bacteriological experimentation with iodized catgut. He also demonstrated an ingenious machine for testing the tensile strength of the gut and comparing it with that of other makes. He stated that the only modification which he had introduced was a very simple, but at the same time, a most important one. It consisted in a step which successfully preserved the tensile strength of the gut. He would prepare it, as originally suggested, by immersing the commercial gut directly into one per cent. iodine and one per cent. potassium iodide solution. It should be left in this mixture for eight days only. His experimental work had demonstrated that absolute sterility was reached before that period, as well as the maximum tensile strength. On the ninth day the latter began to decrease and the gut, if left in the solution longer, rapidly became brittle. The modification which his experimental work had suggested then lay simply in removing the gut on the eighth day and wrapping it in a sterile towel, leaving it to dry until used. If at the time of operation it proved to be a little stiff, a few moments immersion in water would promptly soften it. One of the most remarkable facts demonstrated by the photographic display was that this iodine gut was not merely sterile, but actually produced in infected cultures a sterile zone about itself four times as large as gut prepared by the v. Bergmann method. It should, there-

fore, no longer be looked upon as only mildly antiseptic, but rather as a decidedly vigorous bactericidal agent. This was further proved bacteriologically by soaking iodine gut in virulent cultures of anthrax for twenty-four hours and then placing these infected strands beneath the skin of guinea pigs and rabbits. In no case did the animals die, whereas in every instance in which the v. Bergmann or other forms of prepared catgut were used, the animals perished. The average strength of the iodized catgut, if removed from the solution, on the eighth day was proved by a long series of experiments by the testing machine to be greater than that of the v. Bergmann or any other make. So far as the cost of preparing this material went, the speaker said that one gallon of the solution was worth forty-two cents. As to the disadvantages of iodized catgut, the speaker knew of none. He said it had been suggested that there might be enough iodine in it occasionally to produce toxic symptoms. He had, however, recently been utilizing iodine as a dressing in the wards, and had in every case far exceeded the amount of iodine which could possibly be absorbed by the catgut necessary for sutures in any given case. He had never seen any toxic conditions arise from such use of iodine, and had therefore concluded that this disadvantage was purely suppositional. His conclusions were as follows: Iodine gut prepared in the manner described was always certain to be sterile. It could not infect the tissues even if it were not sterile. It was cheap. It was absorbed at the right time. It was safe and satisfactory in every respect.

**One Hundred and Ten Operations for Femoral Hernia by a Single Method.**—Dr. W. B. DeGarmo presented this paper. He said that he had been working upon this technique for the past fifteen years. He expressed the belief that it was so simple that others must have used it, although he was not aware that any publications presenting it had been given out. Eighty-eight of his patients had single and eleven had double herniæ. Five had femoral and inguinal herniæ operated upon on the same side. The ages of his patients varied from less than ten years to over 80 years. He had had one death and one recurrence which had been caused by persistent vomiting. He emphasized the necessity of using kangaroo tendon and of placing the first stitch through the periosteum of the ramus of the pubic bone. The combined operation in which both femoral and inguinal herniæ were to be cured naturally required a longer incision. He advised that the femoral herniæ should be closed first. The paper was illustrated by a series of sketches which rendered the technique perfectly clear.

Dr. William B. Coley said that no single operator had been able to publish such an extraordinary series of cases of femoral hernia. He said that of his first fifteen cases, one had relapsed. He had in these instances utilized a technique not unlike that presented by the author and which, in his opinion, closely resembled that of Bassini. The remainder of his cases had all been operated upon by the purse-string suture method, and he had been so fortunate as to have no relapses. He recommended the use of an oblique incision, which, in his opinion, gave more liberal exposure of the parts than that endorsed by Dr. De Garmo. His youngest patient was but two months old, and he dwelt upon the fact that whereas every other form of hernia in a child tended to undergo spontaneous cure, if properly supported, femoral hernia had been demonstrated over and over again to be incapable of any cure save by operation.

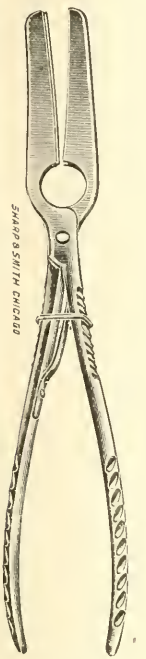
---

**Contraindications of Atropine.**—According to Brav, atropine in ophthalmic practice is contraindicated in glaucoma, in people over forty years of age, and in radial iridodialysis. It should be used with caution in impending perforation from ulcers of the cornea, and in terating children, as it may cause toxic symptoms, and idiosyncrasies are more likely to be encountered. When used locally the preparation should be pure, neutral in reaction, and the lacrymal duct should be closed by compression, or the lid everted, as toxic symptoms may arise through the escape of the drug through the duct into the nose.—*Clinical Review.*

## New Instruments.

### A NEW HEMORRHOIDAL CLAMP.

By HOWARD CRUTCHER, M.D.,
CHICAGO.



Heyworth Building.

In bringing this clamp to the attention of the profession, I do so because it seems to me to possess some qualities that will readily commend it to experienced operators over those now in general use. Of the security of the lock it may be said that it is precisely the same as that employed in the hemostatic clamp that was brought to the notice of the profession through the Medical Record of February 29, 1896. This lock may be operated very quickly, and from the fact that the clamp is generally applied when in the vertical position, is in nearly all cases automatic. It can be released in a fraction of the time required for the older instruments. With other parts of the instrument I have nothing to do; it is the lock that is new, and that consists merely in a steel ring working over serrated shanks.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 16, 1905:

| | Cases | Deaths |
|---|---|---|
| Measles | 72 | 2 |
| Diphtheria and Croup | 172 | 23 |
| Scarlet Fever | 38 | 4 |
| Smallpox | .... | .... |
| Chickenpox | 12 | .... |
| Tuberculosis | 444 | 136 |
| Typhoid Fever | 132 | 22 |
| Cerebrospinal Meningitis | 8 | 15 |
| Typhus Fever | .... | .... |
| Yellow Fever | .... | .... |
| Cholera | .... | .... |
| Totals | 878 | 202 |

**The Status Lymphaticus and the Ductless Glands.**—Roswell Park says that the status lymphaticus is a complicated pathological condition, having much to do with perverted function of the ductless glands, and disturbances of the internal secretions. This condition renders the use of an anesthetic dangerous in many cases, and contraindicates operations, even of a simple character. Sudden death may result from such operations. This condition has much to do with the thymus gland; as it diminishes, lymphoid tissue increases, and the latter tissue assumes the function of the thyroid gland. In marasmus in infants the thyroid is found to have disappeared. Hypertrophy causes more disturbance than atrophy, and when the thymus is enlarged sudden death from an anesthetic is likely to happen. Between the pituitary body, the thymus, thyroid, coccygeal body, testis, ovaries, and bone marrow the relationships are important and not understood. The parathyroids should be included, for their removal causes such symptoms as tetanus, etc., which are produced in experimental myxedema. Their function may be antitoxic. In cystic goiter, where secretion is in excess, the symptoms of exophthalmic goiter are absent, while they are present in other forms of enlarged thyroid. There is strong reason for believing that the secretion of the parathyroids has to do with the nutrition of connective tissue. In the testes are small collections of cells that probably have to do with the growth and development of the body. The testicles have a well marked triple function, production of a substance that has to do with development, a substance necessary to the psychical manifestations of sexual activity, and spermatozoa. The thymus and lymphatics have the most to do with the status lymphaticus. It is commonest in children and young adults, and there is reduced power of resistance to deleterious influences. The thymus begins its involution a few months after birth and should have disappeared at puberty. In the status lymphaticus no involution has occurred. The juice of the thymus contains many leucocytes, and it is credited with producing a secretion similar to that of the ductless glands. Its extract produces fall of blood pressure, dyspnea, and collapse. Enlargement of thyroid produces a peculiar thymic asthma, in which death occurs suddenly. There is always a general hyperplasia of the lymphatic system, spleen, and the Malpighian bodies are packed with cells. The heart may be enlarged and the blood vessel walls thickened. Narrowing of the aorta occurs from infiltration with lymphoid cells. Rickets is nearly allied to the status lymphaticus. The status lymphaticus produces enlargement of lymphoid tissues around the origins of embryonic canals, the appendix, the pharynx, the adenoids, faucial and lingual tonsils. Laryngismus stridulus has to do with this condition. Death occurs generally after a series of convulsions. Before operation we should be sure to eliminate all suspicion of this condition. The use of cocaine and adrenalin before operations on the throat is of value as a prophylactic, in order to deaden the impressions conveyed to the brain. Operation may be possible after appropriate fortifying treatment.—*Surgery, Gynecology, and Obstetrics.*

**On Breathlessness, Especially in Relation to Cardiac Disease.**—Sir Lauder Brunton states that the term breathlessness is sometimes used to signify increased breathing, and at other times distressed or painful breathing. Although these two conditions are essentially distinct, they are so nearly allied that the first easily passes into the second. It is when the heart and lungs fail to aërate the blood sufficiently in spite of all effort that a person becomes conscious of dyspnea. This imperfect aëration may occur either from the air being hindered in its free passage to and from the lungs or from the blood being hindered in its free circulation through the lungs. In dyspnea there are two conditions—the subjective and the objective. The writer then discusses the subject of fatigue. The sensation of fatigue, he declares, may be removed by certain drugs which act upon the nervous system. Cocaine is probably the best known of these. Tea, coffee, beef tea, and tobacco also lessen fatigue; so does alcohol, though its effects are only temporary. Proper massage will generally remove the sensation of fatigue. In discussing cardiac dyspnea the writer states that the great object in attempting to lessen this condition is to facilitate the pulmonary circulaion. The first means for this purpose is absolute rest; the next useful agency is massage. Amongst drugs the most important in its action on the heart is digitalis. The writer advocates its administration by means of the old-fashioned pill containing, besides digitalis, squill and blue pill. He refers to free purgation as a very important means of relieving dyspnea. As to diet, food which will not cause flatulence should be chosen; a milk diet is most useful. When wind is present carminatives must be used to bring it away.—*The Practitioner.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service during the week ending September 16, 1905:

### A STUDY OF FAILURES IN OPHTHALMIC PRACTICE.*

By GEORGE M. GOULD, M.D.,

PHILADELPHIA.

We are all so grateful for gratitude, so happy in our successes in curing, so hurt by our failures to cure, that we are prone to keep our failures out of sight and mind. We report our successes, but it requires a brave man to report his failures with utter frankness. The reporting, the gratitude, and the happiness, however, are by no means so instructive as a close study of the causes of the failures. Of my own cases and those of other oculists whose patients have consulted me, I have lately been making a careful examination, and the results, I think, should be openly confessed. The details of individual cases are too many to set forth, although if time and space permitted I should be glad to do so. But the gathering of them into classes and deducing the laws and lessons of each class will probably be more serviceable than to lose attention in a large number of individual instances.

By failure to cure I mean the failure to relieve those symptoms due to eyestrain. By symptoms of eyestrain I mean many local ocular diseases, such as blepharitis, conjunctivitis, pains in the eyes, asthenopia, heterophoria, choroiditis, retinitis, etc., when these conditions are not evidently due to other causes than eyestrain.

Glaucoma and cataract may be included in the list, although, of course, when established these diseases are not curable by glasses. Preventable, I believe they are. Of capital, cerebral, and mental affections, due usually to eyestrain, I list headaches or migraines of any kinds, localized "neuralgias" and spots of pain, scotoma scintillans, head-tilting, neglect of and disinclination to study, read, etc., foreboding, melancholy, irritability, nervousness, insomnia, illogical conduct, exaggerated desire for physical activity, hysteria, neurasthenia, etc.

Of physical disorders the chief are those classed as dyspepsia, liver disease, constipation, "biliousness," flatulence, vomiting, anorexia, etc. A vast majority of such general denutritional affections are caused by eyestrain, although textbooks on them make no mention of the fact. Attention to the matter with scientific mindedness will probably show that many cases of persistent vomiting, and many of the diseases of the female generative organs have been caused by eyestrain. A famous surgeon says his most brilliant cures of surgical diseases of the pelvic cavity, threatened appendicitis, etc., have been effected through the oculist and his own threatened operations thereby avoided. Almost all of the paroxysmal neuroses may have the same origin, chorea and epilepsy beyond a question. Many a case of functional cardiac disease would find its explanation in the eyes. Of exophthalmic goiter I have little doubt the same could be said. Eczema, hives and anomalous skin diseases certainly attend or follow migraine, and migraine is always due to ocular causes. Haig and his uric acid spook usually means eyestrain. Sometimes the connection, often existing, between circulatory or renal disease and the eyes will be established. Vasomotor ataxia is another name for the nutritional or vasomotor affections which may follow severe eyestrain. The terminal diseases are frequently the servant-executioners of the long-preceding disorders of denutrition, etc., set up by eyestrain.

1. *The want of a single good refraction-school in the world.* Helmholz said that ophthalmology was by far the most accurate and scientific of all the specialties of medicine. I should say that it is now the most inaccurate and unscientific. We all differ from each other. If a patient with a history of migraine, somewhat complicated, and with ametropia and heterophoria, should go independently to one hundred different oculists, I doubt if any two diagnoses and prescriptions would be alike. Only smallpox can vie with eyestrain as a cause of human suffering, but a million more times concern has been devoted to smallpox. Eyestrain causes a thousand times more personal suffering than tuberculosis, and yet the profession and world are a thousand times more interested in eradicating tuberculosis. From 25 to 50 per cent. of our own citizens are afflicted with eyestrain, and yet schools for the study of tropical diseases are multiplying everywhere, whilst there is not one, nor any signs of it, for teaching adequately the art of refraction. Morton's toe is apparently as important as astigmatism. Every refractionist is self-taught, has "picked-up" his science and art as best he could. The "six weeks' course" will no longer avail—except for the quacks. There are physicians out of their true calling in any attempt at refraction work, ill-fitted by nature, but worse-fitted by instruction for an art than which there is none demanding higher intellect or greater skill. The day also of the worship of the scissors or of the ophthalmometer is long in the past. The useful tests, the education of delicate senses and judgment of the student by at least several years of close and special post-graduate study—what Carnegie or Rockefeller, what general physician, has ever cared for this? And without such an institution there will never be an end of our one hundred different prescriptions by one hundred oculists for our patients' evil. The quacks are establishing "optical schools" by the dozen. It concerns us mightily to ask why; but we do not ask why.

2. *Bad case recording* is a source of failure to cure. It may at first seem an absurd *nonsequitur*, but I mean it literally. For many years I was a sinner in this respect, and when I hear or see the reports of others I judge that many are as negligent as I have been. It will not do to jot down the few vague complaints the patient makes. To be sure,

*Read at the meeting of the American Academy of Ophthalmology and Oto-Laryngology, held at Buffalo, N. Y., September 14, 15, and 16, 1905.

leading questions must not mislead. The great fault is not to elicit clear epitomizing statements of all the troubles of the entire life. Only the biographic clinic is valuable in seeking a diagnosis of or in getting a clue to the essential life-trouble or disease. Only that brings the seemingly unrelated phenomena into a clarifying unity. The patient does not dream that "dyspepsia," pain in the shoulders, amenorrhea, cardiac palpitation, inability to sew or read, truancy, "nervous breakdown," etc., may point to eyestrain, and so does not speak of them. When they are cured by glasses, as has taken place in unrecognized thousands, the oculist suspects as little as the patient what was the active therapeutic agent. When they are *not* cured by the oculist he does not reexamine the eyes, does not "stick to his case," until he actually does hit on the right glasses, etc., or until the cause is demonstrated to be of nonocular origin.

3. *The inexpertness, ignorance, or impertinence of the optician* may render all our work and hope of cure in vain. The number of ways in which this may come about is incredible. Examples are the right lens in the left side, or backside front, improperly centered glasses, toric lenses (which reflect 25 per cent. of the light and prevent full stimulus of the retina), and one thousand and one methods of ill-fitting and ill-adjustment. Instead of stiff and rigid spectacle frames, the sole condition of accuracy in position, many opticians have actually been so blunderful as to seek for the most limp and slimpsy thread-like templepieces. No frame should be lighter than 796½ of the American Optical Company. For the majority of noses, and minds behind the noses, eyeglasses are an abomination, even with the most expert optician. Patients will get the bearing in a new place and thus exaggerate instead of lessen eyestrain. In some cases, say two to five per cent., eyeglasses may even be preferable to spectacles. Of course no self-respecting oculist will allow a patient to wear spectacles and glasses he has not seen and pronounced correct. There is needed in every city and village at least one optician who understands his business, is able to do it, and limits himself to doing it. In many places where there should be several or many the incompetence of all is so amazing that to get rightly made and fitted glasses is an utter impossibility. The oculist in such cases does not care, he is not a refractionist, and his optician, of course, is appealing to the legislature to be allowed to become an oculist. The one scorns his proper task, the other aspires to his improper one! *Par nobile fratrum!* This will last just as long as we neglect our duty. We can end it whenever we will. The "eyes-examined-free" man, who cannot fit a pair of glasses any better than he could read the Rosetta stone, exists even in Philadelphia, but he descends lower and lower in disgrace all the time, and we have a large number of expert and honest opticians.

4. *Changes in the patient's refraction,* not followed by changes in glasses, also lead to failures. Once for years I had to change a boy's lenses every few months to keep up with the increasing astigmatism and conquer his pernicious vomiting. Many patients require changes every year, and none should wear the same lenses more than two years. Otherwise, reflexes will appear, one or both eyes grow amblyopic, or heterophoria begin to squint at the muscle-cutters. Constant warnings to patients are necessary to prevent their neglect. I think we should follow the example of the dentists and notify our patients to return for examination as often as we think best.

5. *Incorrect diagnosis of ametropia* appears to be the most frequent source of failure to cure the disorders caused by eyestrain. I do not speak only of those egregious blunderers who think the small error of refraction is not worth noticing, but to those who, although recognizing its astonishing significance, fail to measure the eyeball with mathematic precision, as regards the static errors, the exact amount of myopia, hyperopia, and astigmatism present, and the axes of astigmatism to within five degrees. When my blunder in this has become clear to me and it has cost the patient months or years of suffering I can never forgive myself for the crime. The grievousness of the mistake arises from the fact that the static error of refraction is the primary source, the enduring condition, and the chief cause of all the diseases of eyestrain. It is indeed eyestrain itself, as heterophoria is secondary, and effect, so that failure to measure the ametropia accurately is failure to be worthy of the name of ophthalmologist. If eyestrain plays the havoc in the lives of people which we believe, if from 30 to 50 per cent. of all school children, as we know, have harmful errors, then our failure to do this bit of expert work expertly is our failure to do what we pretend to do. Glaring mistakes in these measurements made even by "specialists in diseases of the eye" are sadly common. Is it not so? Just how common they are each must answer for himself.

6. *Head-tilting,* unless carefully guarded against, prevents the correct placing of the axis of astigmatism. All patients with spinal curvature, completed or organic, are pretty certain to tilt the head to one side, and probably over 25 per cent. of people have some lateral curvature. When the curvature is in the making, that is in the functional stage, the eyes are its cause, either through an axis of astigmatism in the dominant eye that compels the tilt of the head in order to see upright objects, letters of the alphabet, etc., plainly, or when writing to see the "writing-field" about the pen point. Astigmatism estimated with head tilted 10° or 20° to one side is incorrectly estimated by just that 10° or 20°, and will never give the patient relief. Correctly placed the astigmatic axes will tend to straighten the spine in young cases instead of accentuate it, and will relieve the other reflex phenomena.

7. *The morbid writing posture,* due directly to visual function, and inducing perhaps 80 per cent. of lateral curvatures of the spine, is a profound source of our failures. Orthopedists are now recognizing the true cause of this mystery and calamity. The eyes must see what is being written, and usually this is possible only by bending the head and body to the left. All lateral bending of the spine in any part absolutely produces rotation of the vertebræ, at first functional, and then organic curvatures. There result many types of disease and invalidism the cause of which is unrecognized because nobody examines the backs of such patients. In all this astigmatism greatly aids. In the common writing posture of school children the head is not only bent to the left, but it is also bent forward, and also rotated upon its own axis. So that there are three morbid factors in inducing functional malcurvature of the spine. Function always precedes structure; organic morbidity is the result of functional morbidity. Pathology is physiology gone wrong. The child must be taught to sit erect, with head erect; and school-desk, paper-placing must be so ordered that there will be no lateral bending of the head or body in order to see the "writing-field." The functional stage of lateral curvature persists even up to twenty years of age, sometimes later. It may be cured during this period, and may be helped even when, in later years, it becomes organic.

8. *Nonallowance for the patient's personal equations* may frequently account for nonsuccess. The static error found under mydriasis does not dictate the prescription. It is the chief datum, it is true, and any variation from it must be based upon it and kept in mind. But like all dead mathematics the static error must be converted into terms of life and function and modified by a large number of conditions. All vital statistics need vitalizing. The chief and always limiting factors leading to change in prescribing are: change of axis in the astigmatism by the mydriatic; the exophoria or esophoria present; the power, subnormal or supernormal, of accommodation; the age of the patient, the amount and kind and peculiarities of near-work and occupation compelled, the condition of the general health and vitality, the amblyopia from disuse, and others.

9. *The heterophoria-and-tenotomy error* will also sometimes account for failure to cure. One of the saddest tragedies for the implicated physicians, for the profession, for science, and especially for the patients, is the error of tenotomists who have operated for heterophoria. It cannot too often nor too strongly be urged that heterophoria in the vast majority of cases is refractional in origin and innervational in nature. It is generally nature's therapeutic method of obviating eyestrain by throwing one eye out of function. While it is in progress strain may very temporarily be lessened by an operation which partially lessens muscular imbalance. But this does not touch the cause of the mischief, and hence the heterophoria reappears if proper glasses are not ordered, and thus there is final failure. The permanent successes are those in which such ametropic correction is ordered after the operation. It is a crude error, or worse, to credit the operation with the cure, when it was really due to stopping the cause by glasses. Exophoria, or subnormal adduction, is always curable by prism-exercises and proper glasses; esophoria of high degree is not usually curable, but is rare, and I have never seen it cured by tenotomy. Hyperphoria is curable or neutralized by prisms worn permanently with the ametropic correction. Operation cures nothing, even if it reestablishes the muscular balance. But usually it does not do this. It succeeds admirably in one way—financially—for the operator.

10. *The "general-disease" obsession* kills lots of the oculist's patients, or at least confirms them in their pitiful plights. If the origin of their illnesses is eyestrain, all the drugs, rest-cures, travel, wet-packs, etc., at best bring only a temporary and partial relief. It flatters a certain class of minds that they can thank God they are not "hobby-riders," "specialist-exaggerators," etc., and with exquisite fatuousness they affect an immunity to such banal science. But in fact they are the most amusing and capital illustration of specialism gone mad. Of all in the world they discriminate least, and by their aid no patient will ever have the mystery of his disease solved. They walk in the cloudland of glittering generalities, filled with ghosts of "hysteria," "neurasthenia," "uric acid diathesis," "degeneracy," "the pace we lead," "nervous trouble," "dyspepsia," "inherited affection," and the rest, forgetful that such words are not even diagnoses, and surely never therapeutics.

Did the poet have the oculist or the neurologist in mind when he wrote:

> Serene I fold my hands and wait,
> Nor care for wind, or tide or sea;
> I rave no more 'gainst Time or Fate,
> For lo! my own shall come to me.

However, as many astute ones have learned, the oculist's patients will "come to him" only on condition that he "glass" them, and, for general treatment, send them back to the neurologist and general physician (who referred them), and with no hint that the origins of their troubles are, or were, ocular. If dieting, the "rest-cure" or the "trip to the watering-place," the "run to Europe," or "course of strychnine" does good, it is often because the glasses have also been worn, or use of the eyes interdicted. With resumption of ocular labor there is return of all the old troubles. This is because the spectacles were not wholly correct, were incorrectly worn, the refraction changed, or because of many other good reasons. It is of course very impolitic to show the dependence of these diseases upon eyestrain—"his own will cease to come to him"—but if there is one thing more than another that both the American people and profession need it is a flinging of policy to the everlasting bow-wows. Policy and politics are often a vile compound of cowardice and rascality. It can never reach the consciousness of the lay world that the source of so much of its mischief is due to optical defects unless we frankly avow the fact and prove it in the persons of patients. The practical recognition of the fact on the part of neurologists and general physicians seems generally beyond hope. To play the silent helper to them by oculists, and deceive the public, is neither humanly nor professionally honest. There are neurologists and general physicians who prove admirable exceptions to the rule, who still refer their cases to the oculist, frankly saying, "your chief trouble lies in your eyes." They may for a time be in error, as may we also be, but that does not much lessen the average of the truth. Such physicians are lovers of the truth and of their patients. The hope of professional progress lies in them. They also help us oculists to differentiate between true and simulated ocular diseases, and to them we must trust for help in curing the really existing complicating general diseases and in overcoming the terrible results of long-continued morbid function and habits. In most of his patients the specialist deeply needs the help of the general physician, and the two should work together for the good of the patient. But to conceal the truth and deceive the patient as to the real facts is unwise. And in the long run it is impolitic. The game has already been played too long. Anno Domini 1904, in the most famous of American hospitals, patients were treated for astigmatism and for gallstones by the most famous of American physicians, by means of wet-packs. There is hardly a day that patients do not appear in the oculist's office with the most atrocious astigmatism, and whose medical advisers have treated them for ten, twenty or thirty years with no thought or suggestion of eyestrain. They have endured the most awful sufferings, their nervous systems and nutritional organs are possibly wrecked, their eyes may be hopelessly injured, and life so far has been a melancholy tragedy, and all these years the evidence has been before the profession that such diseases might have been prevented if eyestrain had been corrected during youth.

11. *Subnormal accommodation* is one of the most frequent causes of failure to cure our patients of eyestrain glaringly present. The patient's symptoms are brought on by near-work, are not extinguished by the correction for distance, no matter how perfect it is, and the poor oculist is tormented by his inability to bring relief of what is evidently an ocular difficulty. I think a full half of my past failures have been caused by my stupidity in not recognizing the following facts:

The crystalline lens has no nervous connection

with the brain or body, and hence its inherent elasticity, upon which its function depends, fails from infancy to sixty years of age. If we may so speak of it, it fails normally and regularly, so that in comparative emmetropia its failure at forty-five is such that the near point is so far as to make the image of ordinary print and writing so small upon the macula that the retinal and sensation-making task is too great and becomes morbid. The nourishment of the lens is also by blood serum, by osmosis, instead of by red blood corpuscles, and this adds to the inevitable loss of elasticity. What we have failed to notice is that these conditions also make certain a variation in the rate of failure and a difference of primary endowment of elasticity. These two causes would be sufficient to account for the frequency of subnormal accommodation. But there is another source of the mischief more profoundly and commonly present, and this is the fact that in evolution, biology and human history the function of accommodation was brought into existence for only short moments or minutes, always interrupted and rhythmic, especially for the extreme required at a foeal distance of ten, twelve or fourteen inches. Suddenly come sewing, printing, school and literary life, commerce, and a thousand handicrafts which demand for many millions this close-range work and contraction of the ciliary muscle, almost without interruption or rhythm, for hours, for most of the day, for most days, and for most of the life. In no muscle of the body is such uninterrupted innervation and contraction demanded. By none is it possible. The maker of the eye never foresaw civilization. The present demands upon the nervous and muscular mechanisms of the eye in accommodation are beyond the limits of possible physiologic response, and hence eyestrain. The majority of the slaves of civilization require help, beyond the distance correction, in this task, and the need will depend upon the amount of near-work to be done, upon its kind, continuousness, light, etc., upon the initial power or vitality of the accommodation mechanism, etc. Even little children in this sense may be "presbyopic," and one of my most intolerable failures was in a boy of twelve who had persistent vomiting. Immediate and complete cure came at last with + Sph. 1.50 D. added in bifocals, to his distance, correction. I am also convinced that the rate of failure of accommodation varies in different patients, and the subnormality of the two eyes in one patient may differ greatly or even entirely. It is difficult to test the exact degree of subnormality in a given case, and often it is a matter of experiment and doubt. The rough rule has served me that where plus lenses over the distance sharpen the definition of the image of ordinary print at eighteen or twenty inches, subnormality is probably present. It is an elusive mischief, especially in patients with ill-defined, distant, and unexpected reflexes. Careful attention to its possible existence will often solve mysteries and worries in the most brilliant manner. But it will get one into a peck of trouble if the unaided accommodation is sufficient to do the patient's tasks.

12. *"Hysteria."* Among the incurables, those unhelpable either by divine or human means, is the confirmed hysteric. The term is vague and misleading, but it may be used of a strange conglomeration of diahleric, laziness, and mania for sympathy, which torments and pays the rents of fashionable neurologists. In its later stages long-continued malfunction produces genuine morbidity, but as its cherished parents still pamper it, there is little hope of relieving even the direct effects. The woman positively enjoys bad health, escapes from her still biting conscience by excuse and even the pleasure she has in disease, and "takes it out" on husband, father, profession, and civilization by spending as much money as she can, and by demanding more and giving less than any person in the world. She has committed herself to the logical *impasse* of invalidism, and visits with her wrath whoever would open her chosen blind alley to freedom. Eyestrain is peculiarly prone and active in producing the beginnings and the less severe forms of hysteria. "The megrims" was for hundreds of years the other name and perfect synonym of our modern word hysteria; and genuine migraine is the firstborn of the children of astigmatism and light; but it is a great wanderer, and the brothers and sisters are numerous. There is a famous surgeon who it is said has acquired fame and wealth by an unerring caution in refusing to operate upon any patient he cannot cure. The oculist may not—perhaps—follow a similar Mephistophelian plan with chronic hysterical patients. But that would be better than deluding them with false hopes and useless long treatments. Such patients are often morally imbecile, and if one can be sure he can do them no good, that is if they will not obey and do not wish to be cured, it may be best to refuse to waste time upon them. Even the nascent hysteric will usually refuse to wear spectacles, demand eyeglasses, disobey orders, and prefer the *descensus averni* of her pitiless fate. Her parents should have written over her doorway the famous *Lasciate ogni speranza voi chi entrate* of Dante, placed at the entrance of another ill-regulated household. Theirs indeed the fault, and dearly do they pay for it. I have had perhaps a half dozen or more of such inconquerables. Two I cured at the cost of much good life; some I succeeded in ridding myself of; several still remain to bless me and keep me humble!

Genuine neurasthenia appears to be a rare disease and seemingly differing from hysteria in almost every way, although often confounded with it. I know little about it, and suspect others do not know more.

13. *The patient who lives far away* forms one of the types of my failures, and I wish I might never have any whom I cannot see often and easily. Refraction work is highly peculiar in demanding constant attention. There are a score of good reasons for this. The ametropia often changes in a short time; some people never learn to keep their lenses clean, their lashes trimmed, etc., and such things will cause eyestrain as readily as others; the glasses are sure to get awry in all cases, especially if the optician is a "refracting" one, and, of course, refractory; I have had a patient travel five hundred miles to learn that his optician had placed a loose lens front side back; there are a dozen kinds of disobedience to orders and cautions; common-sense rules of ocular hygiene are not to be got into the minds of many patients; no man would pump water an hour, uninterruptedly, with one arm, and yet he expects his eyes to do worse tasks for all day and every day; complicating diseases of the general system arise; mental worry and personal tragedy, of infinite variety, may mimic the symptoms of eyestrain, indeed, are highly prone to do so. The list might be greatly lengthened, but it all comes to this, that disease is always individual, and no rules or habitual methods will replace intellectual acumen and studious differentiation. Therapeutics is the last thing a quack can understand or reach. The distant patient should be put under the care of a local colleague, with frequent consultation between the two. The rise of good refractionists—they are not usually the famous "ophthalmic surgeons," of course

—in most cities, now makes this plan feasible, but small cities still need such men badly. A thousand are wanted in the United States, and all could find work and place at once.

14. *Despairing of curing a patient* may lead to avoidable failure. There is a class of oculists, well represented in every city, who will continue to treat a condition, with care not to cure it, so long as there is money to be made by it—but that is not what I mean. In the great majority of cases of threatened failure or ill-success we become convinced that the mystery has not been cleared up, and that if we were wiser or more painstaking it might be cleared up. In such instances we may grope blindly for an explanation and strike out as aimlessly, hoping that luck may bring us to clearness. Or we may too soon be satisfied that we have made no error in our diagnosis or prescriptions, and coolly tell the patient to go on and relief will come by and by. In other words, we are too confident of our inerrancy, or too despairing of our ability to get at the heart of the matter. There is a great wisdom in going over the tests again and again, in studying the symptoms and the patient more narrowly and from new points of view. I remember once I tortured myself for a year to explain a strange opalescence (with amblyopia, eyestrain, etc.,) of the cornea of an active, seemingly healthy woman. After a number of consultations with others and much worry I accidentally learned the woman was a vegetarian. I succeeded in getting her to eat eggs and meat, and at once the corneas became transparent. I could give the details of surely a hundred cases in which a sort of bulldog determination to hang to the mystery at last revealed some unexpected blunder or new law which brought everything to rights. The plan has the manifest advantage of aiding greatly in discovering new laws. It was in this way that knowledge of subnormal accommodation, head-tilting, the explanation of right-handedness and right-eyedness, the origin of spinal curvature, the eyestrain origin of migraine, etc., came about.

15. *The secondary results of eyestrain* may be too deep-seated, chronic or organic to make cure possible. These, in fact, constitute the saddest of our experiences and failures. I have at once and absolutely cured about ten cases of epilepsy by glasses, but the majority of cases of epilepsy may not be due to ametropia, and certainly the majority of those which had an ocular origin are not to be cured by ocular treatment. So profound and long-standing an injury of the nervous system is not done away with by removing the primary cause. To get at the rat that ate the malt in the house that Jack built we must perhaps go through a long list of subsequent, and at last *per se* existing effects. Eyestrain may beget a condition of denutrition in which tuberculosis or any other constitutional disease secures its foothold. Once established, however, these diseases work their havoc by their own unaided laws. Eyestrain may directly cause gastric anacidity or hypochlorhydria, but, long existent, this may be incurable —even by the tenotomists! The thought leads to the influence of ignored eyestrain in youth or during the plastic and functional stages of disorder. We can do almost anything with the youngsters to reestablish normality and prevent subsequent miseries, but with the wrecks of thirty years which constantly appear in our offices we can only groan, "It might have been." The ignoring prevents prevention. But it is precisely in prevention that our ideals and perfect work lies. No physician can resuscitate the dead, none cure all the effects of organic disease in the living. Even too long-continued functional disease may become so confirmed as to resist all therapeutics, although no discoverable organic lesion is to be found. In their last analysis what indeed is asthma, hay-fever, headache, "latent or concealed gout," angina, melancholia, faddism, incipient or even confirmed insanity, criminality, color-blindness, seasickness, and many other similar affections? The part played by eyestrain in the production of any disorder is less possible to check or extinguish with every added day of its continuance.

But when all has been confessed, discounted, and allowed for, the truth remains that in no department of medicine is practice so satisfying, in none is cure so much the rule, as in refraction work. Even in the inveterate and the most hopeless cases some measure of gratifying and gratitude-bringing relief is usually possible. I would by no means place my failures, all and sundry, all that can rightly be called such, so high as ten per cent. I know of no more astonishing and beautiful thing than the way nature will respond to our intelligent helpings toward cure. The organismal wisdom will often wait, and wait, and still wait, even a lifetime, for the little device which enables her to pick up the tasks and functions deferred by decades of suffering. An eye that has never seen but with one-half acuity because of astigmatism will at once with the cylinder see a new and perfectly visualized world. A heterophoria almost reaching heterotropia will soon disapear. Migraine or sick headache of a half lifetime may suddenly or slowly disappear with proper spectacles. Of course it is not always so, but it is usually so. And the same may be urged as to other systemic effects of eyestrain. The younger the patient the more surely is normality to be reinstated. From 35 to 50 per cent. of school children have sufficient eyestrain to lower their health, put them behind in their classes, or otherwise abnormalize them mentally or physically. There is no duty more sacred than to prevent the certainly-coming tragedies in these children, by the means at our hand. It is in truth a question of national validity, and a concern of civilization itself. The financial value of the communal product can be enhanced by at least 25 per cent. through attention to this, and that is to look at the matter from its crudest and least utilitarian point of view.

## THE TECHNIQUE OF ABDOMINAL SECTION.*

By DENSLOW LEWIS, M.D.,

CHICAGO, ILL.

CHAIRMAN OF THE SECTION ON HYGIENE AND SANITARY SCIENCE OF THE AMERICAN MEDICAL ASSOCIATION.

My thanks are due to the members of this society for the courteous invitation which affords me the opportunity of addressing you. Our fields of activity, geographically considered, are widely separated, but our endeavor is the same. The results of individual work may differ, but they may at times be profitably compared for the benefit of all. As a natural and inevitable consequence of every experience there is evolved and developed a technique which, to each operator, seems to him to be the best. It may not be the best, but it certainly is the best that he knows. It is therefore desirable for the surgeon at times to give evidence of the faith that is in him by an exposition of his methods. He should be prepared to defend every position that he takes; he should have a reason for every detail of his practice; he must, above all things, be able to demonstrate the wisdom of his procedures by successful results.

My first abdominal section was performed some twenty years ago. Dominated by the master mind of Christian Fenger, our efforts to minimize all

*Read by invitation before the San Francisco County Medical Society, July 18, 1905.

danger were most exacting and, were it not for the seriousness of our endeavor, would to-day seem absurd. The patient submitted to a preparatory treatment for a day or two prior to the operation. There were purges and enemeta; there was a carefully selected diet; there were baths and scrubbing of the abdominal wall and external genitals. Finally the patient, half-starved and her intestinal tract well emptied, was enveloped in iodoform gauze, which was removed from the abdomen on the operating table. Now the parts had to be disinfected, the abdominal wall was scrubbed with vigor and various antiseptics were used. The operator's hands were subjected also to severe disinfection, which necessitated the use of soap and water, carbolic and bichloride solutions, and sometimes solutions of permanganate of potassium and oxalic acid as well. The operator and his assistants and nurses were dressed in costumes that resembled bathing suits. I remember I had taken a Turkish bath and a shampoo. Live steam escaped in the operating room so that we could scarcely see across the table. A spray of carbolic acid played in one corner of the room, but we had at that time revolted to some extent against Lister's recommendation, so that the spray was not directed on the patient's abdomen. It was deemed essential to kill all pathogenic bacteria which were supposed to be omnipresent and, flying around, as it had been graphically expressed, like the birds of the air, were presumably intent on fulfilling their mission of destruction. It was considered advisable to diminish shock and to spare the peritoneum all outrage to abnormal conditions. For that reason the temperature of the room approximated the temperature of the body, the incision was as short as possible, and the element of time was of great importance. Moreover, it was considered undignified, or at least to some extent a confession of incompetency to look into the abdominal cavity. Much had been said and written, and I think Lawson Tait and my friend Howard Kelly were to some extent responsible for the prevalence of this idea about the *tactus eruditus*. The experienced operator, and even at that time it was claimed no other should dare to invade the abdominal cavity, was supposed to insert his hand and at once feel the offending pathological condition and bring it up into view so that it could be cut away after its pedicle had been ligated. Opinion differed regarding drainage and the toilet of the peritoneum. Oftentimes hot water was poured in by the pitcherful. The abdominal wound was usually closed by through-and-through sutures, and opium was often given to relieve pain and keep the parts at rest so they might heal kindly.

To-day all this is changed. The preparatory treatment consists of a bath at admission, a compound cathartic pill at night, a dose of salts in the morning and an enema just before the operation, at which time the catheter is passed. The patient's abdomen is often palpated by students just before the operation and the disinfection of the abdominal wall occurs during or just after the anesthesia. Soapsuds and hot water are used by means of a brush for perhaps two minutes, and the surface is wiped dry with a sterile towel. A bichloride solution is then applied by means of a gauze sponge, and finally alcohol is poured on. The operator's hands are prepared in the same manner, care being taken to have the nails clean and to scrub between the fingers. The procedure takes perhaps three minutes. The incision is made long enough to see exactly the condition of tubes, ovaries, and other organs, and with the patient in the Trendelenburg position and a large laparotomy sponge holding the intestines out of the way, the edges of the wound are retracted and we proceed deliberately and calmly to operate by sight as we would do if we were operating on the back of the hand.

The incision is preferably in the linea alba, but wherever made bleeding vessels should be caught with forceps and often ligated with fine catgut, so that all hemorrhage is controlled as the incision is extended. The bleeding vessel in each instance should be seized alone, with as little of the adjacent tissue as possible. I have opened and closed the abdomen at least five hundred times without the use of hemostatic measures of any kind, except forcible compression by gauze sponges and through-and-through sutures. I do not now favor this procedure. I believe it to be the part of wisdom to save every drop of blood, for no one can tell how much may be lost accidentally toward the close of the operation, nor can it be denied that every minute bloodclot in the abdominal wound is an additional factor of importance as a potential nidus of infection. I also believe it to be advisable to secure accurate coaptation of the several structures of the abdominal wall, so that a true *restitutio ad integrum* may really occur. This is only possible by actually bringing together by suture the different tissues so that peritoneum may be apposed to peritoneum, aponeurosis may be united to aponeurosis, the continuity of the musculature may be restored, the superficial fascia may be brought together, and finally the cut edges of the skin may be accurately apposed without undue tension. For this purpose I favor the use of sterile catgut, which is now obtainable, and the separate approximation, preferably by individual suture, of the different tissues which constitute the abdominal wall.[1]

The after-treatment is of importance. I give no opium, and only occasionally, in case of great restlessness, a dose or two of twenty grains of sodium bromide by the mouth, or the same quantity of chloral by the rectum. The bowels should be made to move early. I am in the habit of exhibiting one-eighth grain doses of calomel every hour the morning of the second day until perhaps eight doses are taken, to be followed by what we call a one-two-three enema, which consists of one ounce of magnesium sulphate, two ounces of glycerin, and three ounces of water. This is injected high up in the bowels, and if it does not act there is cause for alarm. After the bowels have been moved once the regularity of bowel movement is maintained by giving fluid extract of cascara sagrada in suitable doses—usually fifteen to twenty drops three times a day—supplemented, if necessary, by a daily saline enema. Cases that were *in extremis* at the time of operation may require hypodermic injections of strychnine every few hours for a few days. Thirst is relieved by normal salt enemata, given several times a day—about a pint at a time to be retained. Retching and vomiting do not often occur to a distressing extent, and disappear as a rule when the bowels move. Tympanites is rarely observed, but at times may necessitate the insertion of the rectal tube to facilitate the escape of gas. If the uncomfortable symptoms persist, if the pulse rate is high, and pain is severe, it is inadvisable to mask the symptoms by the exhibition of digitalis or sedatives. There is a cause for the persistence of these unfavorable symptoms, and usually they mean an infection within the peritoneal cavity which may necessitate a reopening of the abdominal wound. In any event it is folly to deceive ourselves by the control of pulse, temperature, and pain by means of drugs, when the real cause of a deviation from a normal convalescence usually requires surgical intervention.

Regarding the technique of the different abdominal operations that are now performed, it is of course impossible for me within the time at my disposal to speak in any adequate manner. I will, however, with your indulgence, allude to my individual preference in some of the procedures that are incidental to the more usual abdominal operations. Catgut alone should be used within the abdominal and pelvic cavities. It is safe nowadays, that is, it is just as likely to be sterile as silk. No unnecessary amount should be used, for at best it is a foreign body which must become absorbed or encysted. In removing a tube the parts should not be bunched up and transfixed or tied off with the Staffordshire knot. The tube should be cut into at its uterine attachment and the end of the ovarian artery that is cut across should be seized with a small forceps and ligated with fine catgut. It is my practice at once to sew over the uterine peritoneum by means of a continuous suture of fine catgut, and as the tube, the cut end of which is held in the bite of a medium-sized forceps, is cut away I continue the suture of the peritoneum of the broad ligament until the operation is completed. In every case the effort should be made that no raw surfaces are left exposed to favor adhesion that may predispose to ileus. When the operation is completed I insist, as I have done for years, that nothing but peritoneum should be apposed to peritoneum within the peritoneal cavity.[2] In operating for pyosalpinx or ovarian abscess or cyst the incision may begin at the distal or proximal end, but in every case the peritoneum should be turned in by a continuous catgut suture as we proceed or, if interrupted sutures are used, they should finally be buried. If omental adhesions are evident when the abdomen is opened, they may satisfactorily be separated by Downs' cautery,[28] but if cut through the edges should be covered with peritoneum before proceeding. I take occasion here to refer to the advisability of leaving a portion of at least one ovary, unless both are hopelessly diseased. The discomfort incident to a premature menopause is real and often distressing, and the nervous instability that may result not infrequently leads to permanent mental aberration.

The technique of uterosuspension and the many operations that are proposed and practised for the correction of uterine displacements I will not attempt to describe, because I disapprove of nearly all of them. I have already pointed out[26] that subinvolution infection and its sequelæ and different pathological conditions are responsible for most cases of so-called malposition, and I have always maintained that operations which did not restore the parts in accordance with normal anatomy were, to say the least, irrational. Many cases in my practice continue to prove to me that the relief of pathological conditions results in symptomatic cure, and if the variation of the uterus from its assumed normal position is not corrected as a consequence of treatment instituted against the true etiological factors, experience demonstrates that health and function are restored. The traumatism that produces displacement is usually an injury to the levator ani muscle and the aponeurotic tissue in direct relation to it. Restoration of these parts in any part of the periphery of the muscle is anatomically possible, as I have proved on the cadaver. The application of the true principle of restoration, well enunciated by Goldspohn[27] in reference to perineorrhaphy, will in time, I believe, be applied to intrapelvic procedures with equally satisfactory results. My individual experience along these lines is as yet too limited to permit of any recommendation.

In many instances where suppuration is apparent the exact condition is not known until the abdomen is opened. When the abscess cavity is recognized we should pause and consider what technique is best for the patient. Of course it may be admitted that in every case it is possible to provide an outlet for the pus. In doing so there must be the minimum of danger to the patient's life. If adhesions are numerous and firm, it is often the part of wisdom to place the patient in the exaggerated lithotomy position and perform a vaginal section simply for the evacuation of the pus. Such an operation may be incomplete, but it is often successful. It may not be very scientific, but it often saves the patient's life when a more extensive procedure might be fatal. In old cases, where the edges of the abscess cavity have been stitched to the abdominal wound and a sinus results, in cases where drainage has been employed and suppuration continues, or, it may be, a fecal fistula has formed, I have often derived benefit from passing through the opening in the abdominal wall a large, curved forceps, so that its point could be cut down upon from the vaginal fornix and a large drainage tube inserted.[3] Irrigation is now practicable; within a few days the discharge of feces usually ceases as the opening into the intestine heals; the discharge of pus diminishes, and in many instances the opening is obliterated. When suppuration persists under these conditions an infected ligature is apt to be at fault. Here suppuration will often continue until the offending bit of silk or catgut is washed away. The effect, however, of the establishment of counter-drainage is usually apparent at once. Temperature falls, the general condition of the patient improves, suppuration diminishes, the walls of the abscess cavity become proximated and, as the drain is replaced by a smaller one, and eventually by a few strands of silkworm gut, the parts will usually heal.[4] Should there be delay, or should it become apparent that more radical measures are necessary to close an intestinal opening or to cut away an infected area, the counter-drainage will have been of value in limiting the extent of suppuration and in permitting an improvement in the patient's general health, so that the chances for a successful secondary operation are increased.

In what may to-day be called neglected appendicitis—I refer to cases where an abscess has formed—it is often wise not to attempt to do too much. I know I invite criticism by this statement. I realize to what an extent Joseph Price and others have insisted upon a complete operation.[5] I believe, however, it is often best to provide drainage and not run the risk of infecting the general peritoneal cavity by injudicious manipulation at this time. If further operative procedure becomes necessary in the future for the relief of hernia or for the closure of a sinus the patient will at least be alive to submit to it, whereas in too many instances an extended primary operation will have resulted in death.

Suppuration in the course of a peritonitis must receive surgical treatment or the great mortality from that disease will continue. When abscesses occur between kinks of intestines, or in relationship with any of the pelvic or abdominal viscera, the pus must be evacuated at the earliest possible moment and usually a Mikulicz drain inserted. I look for much improvement during the next few years in our treatment of peritonitis. I believe we will drain more often and more thoroughly whenever there is pus, toxins, or debris, and I am inclined to think that irrigation—even continuous irrigation with the patient in the Fowler position[6]—will more frequently be found of value. I cannot agree with Olshausen that drainage is usually contraindicated

or ineffectual.[7] I use a hot salt solution very often to control inaccessible hemorrhage and to combat shock, and I have several times left in the peritoneal cavity a pint or so of a very hot solution when all septic matter could not be removed or when raw surfaces could not be covered with peritoneum.

In the separation of adhesions it may happen that the intestine will rupture. This is not always the fault of the operator, for sometimes the parts are gangrenous or so badly ulcerated that rupture is inevitable. When this accident occurs the opening in the bowel should be closed at once, using interrupted sutures for the muscular and mucous coats, and a continuous Lembert suture for the peritoneum, being careful to turn in a relatively large amount. In certain instances, and my remarks here apply also to traumatic cases, the injury to the bowel is multiple or the ulceration is extensive, so that resection becomes advisable. Under these conditions the value of the Murphy button has been often demonstrated, both because it is quickly and easily adjusted and because the results are good. When the condition of the patient permits and the operator is accustomed to abdominal work I prefer the closure of both ends of the bowel and a lateral anastomosis. I wish to make no fanciful discrimination here, but it is a fact that the element of time in these cases is often of value, and the element of experience often turns the scale in one direction or the other. For this reason I have urged the necessity of a modicum of practical knowledge of abdominal surgery on the part of every practitioner, no matter what his specialty may be, for no one can tell when a little scientific sewing may save a human life. Intestinal needles should be in every man's instrument case, and the confidence gained by even one experiment on a living animal is well-nigh invaluable. Emergencies in abdominal cases are probably not more frequent now than in the past, but the consensus of modern professional opinion demands today an exploratory incision in many instances where formerly the fear of infection or the imagined difficulty and danger of laparotomy left the patient to die. In cases of presumed obstruction, in gunshot and stab-wound cases, in serious injuries, even where there is no penetration, in perforation of the stomach or duodenum, or in typhoid perforation, there should be no hesitation, for statistics show that death is often inevitable without surgical intervention. In any event, an aseptic abdominal section performed even by a practitioner who has not a record of successful operations to his credit will not add to the risk, and may be the only means of saving life.

In all traumatic cases and in many of the others I favor a few cigarette drains for at least twenty-four hours.[8] In the typhoid cases I venture the prediction that the operation in the future will consist of something more than the purse-string closure of the perforation. Typhoid lesions are apt to be multiple, and the ulceration that exists is apt to be extensive, so that the integrity of the bowel is threatened. For that reason I believe future operations will more often include a resection of all diseased tissue. As a final word in this class of cases I most cordially commend the statement of C. B. Keetley,[9] who asserts that any physician who wastes valuable time in the attempt to make an accurate diagnosis is almost criminally responsible for the death which is sure to follow. His remarks, made in reference to gastric ulcer when there is vomiting of blood, acute anemia, quick and progressively weak pulse, and other alarming symptoms, I apply to all abdominal cases where the outcome is uncertain and where an incision may reveal the true pathological condition.

In obstetric practice the indications for abdominal section are becoming more evident and the technique is being well worked out. Rupture of an ectopic gestation means hemorrhage, and usually demands an immediate operation to permit the ligature of the bleeding vessel. Delay may mean death in a few hours, as I know from experience, even when the symptoms are not alarming. For that reason the possibility of pregnancy should be remembered in the case of every female, married or single, between the ages of twelve and fifty-five years, and the occurrence of fainting, slight indefinite abdominal pain, yawning, and increasing pallor, even in the absence of increased pulse rate and what are usually regarded as pathognomonic symptoms of internal hemorrhage, should at least direct attention to the suspicion of an accident of this kind, and should warrant intelligent and watchful surveillance.

A wideawake supervision and a realization of the possibilities are essential in all cases where an interruption of pregnancy is threatened or has taken place. In too many instances the abortion is criminal, and the infection or trauma may require operative treatment. In the former case abdominal section may usually be replaced by a vaginal incision to facilitate the escape of toxins, as Pryor has explained.[10] When, however, a uterine perforation is evident, especially, as in one of my cases,[11] when a silver catheter had been forced through into the peritoneal cavity, an abdominal incision alone permits a search for the foreign body and its removal, as well as the closure of the uterine wound.[12] In late cases of infection following labor abdominal section is sometimes necessary, for the placental site favors an extension of infection, and at times hysterectomy must be performed. There is also the possibility, as occurred to me once, of finding an unsuspected appendicitis.[13]

Rupture of the uterus occurs oftener than imagined. There are too many fatal cases of delayed labor from one cause or another, too many cases of version that end fatally, and, if the truth were known, as it is not very often, it would be found that the cause of death was a rupture which perhaps had not been suspected. Modern Cesarean section and the results obtained from its timely performance all over the world show us our mistakes of the past and indicate the proper procedure for the future. Olshausen's technique is simple and most successful. I saw fourteen cases in his practice during one year—all the infants living and all but one of the mothers. The technique is simple, and though I have already described it,[14] I will here say that the pregnant uterus is brought forward out through the abdominal incision and held there by an assistant, who steadies it while the incision is being made and the child and placenta are extracted, and who, by the pressure of his two hands laid flat on the abdomen, prevents the uterus from slipping back and controls undue hemorrhage until the sutures are placed and retraction has occurred.

Unfortunately the days of meddlesome midwifery are not yet past, nor has the time yet arrived when there is made in every obstetrical case a scientific prognosis based upon accurate pelvic measurements and due appreciation of existing conditions. When that time comes we will know the possibilities in every case, and we will not persist in efforts at delivery when the mechanical obstacle is plainly insuperable. We will not delay nor run the risk of traumatism nor of infection with all that it means at the time of labor. We will perform an abdominal section, which is not only true conservatism, but a real prophylaxis.

The operation to be done is of course the modern

so-called Sänger cesarean section. The Porro operation, which ten years ago I advised as the operation of choice,[15] should now, in my judgment, be reserved almost exclusively for cases of rupture where a repair of the injury is impracticable.

These cases of rupture occur not only in obstetric practice, but also as the result of traumatism during pregnancy. As causes I find records of falls,[16] pumping,[17] crushing,[18] a kick in the right groin,[19] a nail in the backboard of a wagon,[20] and a number of cases due to cattle-horn, bullet, and stab-wound injuries.[21] It is recognized to-day that an abdominal section is the only procedure to be considered where there is penetration due to traumatism,[22] or where the injury is serious enough to warrant the assumption that internal rupture may have taken place.[23] The technique will include the repair of injured viscera—the ligation of bleeding vessels, wherever found, the closure of intestinal or uterine wounds, and if necessary the resection of intestines, the supravaginal amputation of the uterus or the removal of the entire uterus, as first performed in a case of rupture by Prévot, of Moscow.[24]

In the case of large fibroids of the uterus supravaginal amputation is preferable to hysterectomy. If a portion of one ovary can be left, menstruation occurs from the mucous membrane of the portio vaginalis. Indeed, one of my patients called on me some years after the operation to inquire if pregnancy was possible. As a general proposition I favor the enucleation of fibroids in young women. It is simple to incise the capsule, shell out the tumors, and sew up the space with several rows of buried sutures, the final suture being a Lembert, which turns in the peritoneal surface. In this manner I have seen Olshausen remove seven tumors from one uterus. Where the mass is large and the tumors are multiple, so that their removal seems impracticable, especially if the woman be middle-aged, supravaginal amputation is indicated. It is performed by ligating the ovarian and uterine arteries and any other bleeding vessels, and by closing the incisions in the broad ligaments in the manner I have already indicated. The uterus is then cut away about at its juncture with the vagina, and the stump is closed with two or three rows of sutures which approximate the musculature and finally close the peritoneal incision. In this manner hemostasis is complete and there results a smooth peritoneal surface.

Carcinoma of the uterus is usually removed by vaginal hysterectomy and, all things considered, perhaps to-day it is the safest and best procedure to be recommended. At the same time, the complete evacuation (ausräumung) of the pelvis, as performed by Mackenrodt,[29] is theoretically most attractive. I have seen him operate in eight cases with good immediate result, but the operation is most difficult and tedious, and his cases are as yet too few and too recent to warrant an unqualified endorsement. The technique I have elsewhere described.[25]

My reference to operative technique in relation to the viscera of the superior zone of the abdomen will be brief. Gastroenterostomy should be performed more frequently, for increased experience demonstrates its value, not only in cases of ulcer and carcinoma, but especially in chronic cases of indigestion. Statistics seem to show that the anterior operation is not only the simpler, but usually the more satisfactory procedure. Drainage of the stomach and the placing at rest of an infected mucous surface offer relief in many instances where lavage and continued medication have been ineffectual. Gall-bladder surgery has made important advances of late years. Calculi are proved to be not the only offending pathological condition. In many instances the separation of adhesions and the systematic drainage of the gall-bladder produce most gratifying relief. In every case the common duct should be examined, and not infrequently it will be practicable to sew up an incision made here for the removal of a calculus.

In conclusion let me say that this brief and necessarily incomplete reference to certain technicalities of operative procedure is intended to set forth the advisability of systematic work through an incision large enough to see and feel the true conditions. It favors perfect hemostasis as the operation proceeds. It advocates the turning in of all raw surfaces, so that only the smooth peritoneum is left when the operation is ended. In pus cases it advises removal with the least possible danger. In a word, while completeness of operative technique is commended, it must never be forgotten that the saving of the patient's life is more important than brilliant surgical treatment. With that end in view every compromise must be made to avoid unnecessary risk, and no chances must be taken which will jeopardize the main interests at stake.

# COUNTERIRRITATION.

By JOHN W. WAINWRIGHT, M.D.,

NEW YORK.

Counterirritation is a therapeutic measure which has come down to us from the earliest writers—from great antiquity. The rationale of its action is, however, no better understood to-day than centuries ago.

Local irritation cannot exist without causing certain general changes which affect the entire organism. Head found that in many cases internal disease is accompanied by a tenderness of the skin, and he mapped out carefully the skin areas corresponding to each organ. In this way he was able to show that a distinct relation exists between irritation of an internal organ and that part of the skin which is supplied by the same segment of the spinal cord or brain. Thus in painful diseases the tenderness is not infrequently referred to a position other than the seat of the disease. The observations of Head show that a nervous impulse from the diseased organs does not pass in an indeterminate manner through the central nervous system, but has a distinct tendency to affect the superficial areas which are supplied with sensory nerves from the same segment of the cord. If it could be shown—and as a theory it appears sufficiently plausible—that an affection of these superficial areas may affect the corresponding internal organ more than the rest of the body, then a satisfactory explanation of the benefits derived from the use of counterirritants would be afforded.

Small thinks that probably the most correct explanation of the action of the counterirritation is that which looks to the sensitiveness of the cutaneous nerves and their reflex action upon the deeper parts.

Counterirritation is resorted to for three objects: to relieve pain, to lessen congestion and inflammation of deep-seated organs, and to promote the absorption of the products of inflammation. That it has merit will be generally conceded. Like bleeding, cupping, leeching, and numerous other forms of treatment practised in earlier times, it has fallen into disrepute, but surely counterirritation does affect the internal morbid processes; how, is not for us here to discuss. Counterirritants are divided into rubefacients, vesicants, and pustulants. The first do not destroy the structure of the skin, and are such as cause a mild irritation and redness; they are employed only in functional disturbances. The second cause structural changes in the skin and underlying tissues, and are used in chronic affections or when inflammation has preceded a permanent change in the organs or tissues. Mustard plasters, pepper, iodine, turpentine, etc., are typical rubefacients, while the actual cautery, caustics, issues, setons, etc., are known as vesicants. The third cause pustular eruption; croton oil and tartrated antimony are the best known of this group. Croton oil is the pustulant generally used, but it must be diluted one-half with olive oil or spirits. The course of the eruption is similar to the eruptive stage of smallpox. Because of the disfigurement liable to follow the employment of pustulants, discretion must be exercised in their use.

The local effect of the rubefacients is the same as that of acute inflammation, the pain being due to irritation of the nerve terminals; the redness and edema to dilatation of the blood vessels, edema following the disturbed and retarded flow of blood and consequently the transudation of the fluids into the tissues, thus producing at the point of greatest irritation a blister. A continuous irritation is followed by suppuration. Because of this fact the physician is enabled to get a more profound effect in deep-seated organs or parts where counterirritation is resorted to as a therapeutic measure to correct the effects of permanent change through inflammatory processes, such as pleuritis, peritonitis, and pneumonia. Blisters are, however, contraindicated in the aged, in gout, diabetes, and in debilitated or anemic conditions, for the reason that sloughing is to be feared. In chronic inflammatory conditions with effusion, counterirritation will be found serviceable, through an improvement in the circulation. Chronic ulcers are often made to take on the reparative processes through the use of irritants. The repair in bruises is hastened by the use of counterirritants such as tincture of iodine and stimulating embrocations when there is not a destruction of tissue. In certain forms of skin diseases, especially those of a chronic character, like acne, the use of irritating or stimulating applications is often of service when all other means have failed. In gastric disorders with severe pain, in colics, neuralgia, neuritis, especially the sciatic or rheumatic form, they are often of great service. Again, in collapse and shock through reflex action they give gratifying results. In internal hemorrhage, by directing the blood from the seat of injury to the surface temporary relief is often obtained.

Sawyer recommends the use of a preparation of capsicum as a rubefacient counterirritant. He has found that an ethereal tincture of capsicum, by reason of the comparatively rapid evaporation of its ether, can be used more freely than an alcoholic tincture, as an application to the skin. Further, the solvent action of ether upon the sebaceous secretion of the skin makes ether a menstruum preferable to alcohol for drugs designed to affect the cutaneous surfaces, or to produce therapeutic effect through the skin. An excellent and powerful rubefacient liniment may be made of equal parts of ethereal tincture of capsicum, liquor ammoniæ, oleum terebinthinæ, and oleum lini. This liniment may also be applied to the skin upon spongiopiline.

Caution should be exercised in applying blisters at the beginning of inflammatory processes or in the acute stage. Never to the scrotum or mamma, nor over bony prominences, as the process of healing will be slow and difficult. Blisters should be avoided in the case of a pregnant woman. In infants or young children there should be placed between the skin and the blister a piece of oiled muslin in order to prevent too serious injury to the integument.

Blisters were formerly used in epilepsy to arrest the aura. They were said to act by adding a new irritation, which counteracted the preexisting irritation. In incontinence of urine a blister applied to the sacrum will often succeed when other measures have failed. Again, in otitis, a cantharidal blister applied behind the ear is a popular measure.

The following suggestions concerning the employment of the fly blister are contained in the *Medical World:* "The fly blister is of value for four purposes: To affect inflammation or congestion; to cause absorption or removal of inflammatory deposits after inflammation has ceased; to relieve pain; for the effect which can be exerted upon the general system by blisters in systemic disease."

When used to affect inflammation, the blister should not be applied over the site of inflammation, but should be placed a little to one side or at some other point known to be intimately connected by nerve fibers with the seat of inflammation; thus, in inflammation about the eye, the blister is applied back of the ear; and in pleurisy or abdominal neuralgia the chosen site of application is over the vertebra where the nerve at fault makes its exit. Remember that all nerve pain is referred to the peri-

pheral end, and not to the point of origin. In beginning hip-disease it would be useless to apply a blister to the knee or ankle complained of, but good results are often secured by applying it over the proper place in the affected hip. A fly blister should never be placed directly over the site of an acute inflammation; when it is to be used in such cases, apply it in a circle around the inflamed area, at a little distance. The fly blister does good service in inflammation of the brain, eye, pleura, peritoneum, lung, joint (rheumatic or traumatic), glands, uretha (gleet), etc. The old view, that fever was a contraindication to blistering has faded away. One exception should be made in the rule of locating the blister; in peritonitis apply it directly over the seat of pain. In gleet, cantharidal collodion may be substituted for the blister, and used by painting along the under side of the penis and on the perineum.

To remove the results of inflammation, such as pleurisy with effusion, the fly blister is extremely valuable; in such cases apply it under the arm about two or three inches below the axilla. In old effusions about joints the blister often succeeds where other means have failed.

The indications for the relief of pain will be plain to all. It is only in chronic pain that the blister is proper, and such rubefacients as mustard plasters generally do fully as well and do not leave such an amount of tenderness.

To get systemic effect one must study each individual case before applying the blister. In meningitis apply in T-shape to the back of the neck; in intercostal neuralgia and zoster, to one side of the spinal column; in renal irritation, between the kidneys over the spine, etc.

As the blister begins to form, remove the fly blister and apply a warm poultice; this relieves the pain and hastens the process. If the blisters are small, they may be allowed to rupture spontaneously, but if large they should be punctured at the most dependent part and dressed with sweet oil or simple ointment carbolized in the strength of 1-100.

Issues and setons are rarely made use of to-day, and excepting in the case of certain disturbances of the eyes the same may be said of caustics and escharotics. We may therefore safely pass them by with a few words. Issues and setons were used in the earliest times, through the belief that they relieved the system from a tendency to disease, as it was thought a discharge from ulcers did. Serious and fatal effects were often attributed to the closing of these "natural discharges" by spontaneous or artificial means. They were considered measures suitable to chronic diseases only, and acted as derivatives and evacuants. They were used in asthma, catarrh, deafness, and epilepsy, in chronic cerebral and spinal affections (induced in the back of the neck), in chronic affections of the eyes (induced in the temple), in uterine affections and chronic cystitis (induced above the pubis), in chronic affections of the joints (induced in the neighborhood of the joint), etc.

The actual cautery is one of the best means of establishing counterirritation. The thermocautery is generally employed.

Blood-letting, either venous or arterial, was formerly largely practised, as well as leeching, cupping, and scarification, the object being (1) to weaken the action of the heart and consequently the force of the circulation; (2) to lessen the quantity of blood in the system; (3) to cause a derivation of blood from other parts to that whence the blood issued; (4) to promote the absorption of medicines internally administered; (5) to impoverish the blood and its content of fibrin and globules.

Poultices are useful to relieve congestions, to reduce inflammations, to promote absorption, favor resolution, or hasten suppuration; to diminish tension, soften incrustations, stimulate healthy granulations, and as deodorants and antiseptics. Their use should not be continued long enough to produce anemia or a too relaxed condition of the parts, for fear of necrosis of the tissue; nor should a poultice be often used after an evacuation of pus.

They should be applied hot, moist, and not too heavy; between folds of gauze or muslin and covered with cotton. A bandage may be used to keep the poultice in place. They should be made of sufficient size to cover the inflamed area and changed from time to time as they become cool, until the inflammation has in a measure subsided or until there is softening of the tissues and pus formation. They may be made of flaxseed meal, bread, corn meal, slippery elm, charcoal, soap, etc. When a stimulating effect is desired, various ground spices may be added, or used alone by mixing in a muslin bag, moistening in hot water or some alcoholic preparation, and applied hot.

Charcoal poultices are useful in gangrenous conditions when there is generally a disagreeable odor. They are made by sprinkling the powdered wood charcoal over a flaxseed or bread poultice, one part to two or three parts by weight of flaxseed or bread, or a mixture of both flaxseed and bread. Apply direct to wound and change frequently. Antiseptic poultices can be used upon foul ulcers, etc.; they are made by adding an antiseptic fluid to the flaxseed or bread poultice.

Soap poultices are used in preparing the skin for surgical operations. Green soap is preferred, and is applied in a thin paste spread upon gauze.

Digitalis poultices are used when there is retention of the urine; they are prepared by sprinkling powdered digitalis upon flaxseed poultices and applying hot and moist over the pubis.

177 West Eighty-third Street.

## Some Notes on Typhoid Fever in the Philippines.

By William Duffield Bell, M.D.,

Watertown, Conn.,

Late Major and Surgeon, U. S. Volunteers.

Typhoid fever is one of the many diseases prevalent in the Philippines which are preventable where honest enforcement of quarantine regulations is allowed to replace the ignorance and hostility of a native population. No field is open to the medical officer in which so much good can be accomplished as lies before the authorities in the Philippine Islands, where the intelligent and faithful enforcement of sanitary regulations can secure such beneficent results. Typhoid can be stamped out as well as cholera, and the endemic spots which dot the entire islands, and from which emanates the deadly poison, can be readily eliminated. The work must be done by intelligent and reliable white men and not by natives, upon whom little or no confidence can be placed. It is not the climate of the Philippine Islands that plays an important factor in the development and continuance of typhoid fever. The heat of the dry season, which covers the months of February, March, April, and May, reaches a mean temperature of 87°, May being the hottest month of the year. The rainy season from June to October has a mean temperature of only 84°. While the cool season, with a temperature of 72°, is the one during which the greatest mortality occurs among the natives, and it is during this period, when

their systems present the least powers of resistance, that they succumb so readily to typhoid. It is not the heat of the tropics, or rather it is the continuance of the heat that renders the system less prone to offer the required resistance to disease, rather than the degree of heat. The real cause there is the fruitful soil for the propagation of the typhoid germs, which the universal filth that surrounds the houses of all Filipinos furnishes, the houses within and without alike being steeped in filth. No disposition is made of human excrement other than to allow it to fall beneath the house, where the scavengers are the dog, the chicken, and the pig. No sewerage drains the accumulation of filth except the surface drainage, and the well or stream from whence the water for drinking purposes is procured can scarcely be regarded as other than a fruitful source of disease. Water so polluted is used with utter disregard, and typhoid fever, a water-borne disease, is clearly given a chance to spread. Polluted wells and streams furnish the potable water, and only by the most stringent regulations, enforced with severity, can they ever be kept free from contamination when once they can be cleansed, for one cannot overcome the benighted ignorance of centuries in a few years.

The spread of the disease through the use of milk is a minor factor, for the reason that there is little or no milk to be had in the Philippines; the carabao, or water-cow, and the goat furnishing the only source of milk supply throughout the islands, with the exception of the limited supply of milk brought from Australia. One case of typhoid fever among the natives of a Philippine village becomes a focus of disease, and goes to start one of the epidemics of typhoid fever so often met with under the name of "calenture," when a careful investigation shows the presence of a typhoid epidemic. A residence of over one year in the town of Morong, Province of Rizal, in the center of the southern portion of the Island of Luzon, the most northern of the larger islands of the Philipines, gave an opportunity for a close observation of this and other diseases among the native population. Here, among the native population of a town of about eight thousand inhabitants, typhoid fever existed throughout the entire year, the greatest number of cases occurring in the months of November, December, and January. And here, as in the United States, the greatest mortality occurred during the first quarter of the year. The reason for this is that the power of resistance of the natives is at the lowest ebb at the close of the cold season. This is because of their insufficient sustenance and the imperfect protection offered by their clothing against the cold, which seems trivial to the better-clad and better-fed American, or other white man. To an American it seems absurd that people should suffer and even perish from cold in a temperature seldom below 70°, but such is the case. The men of this town appeared to suffer much more readily from the disease than the women, and while the pregnant and the plethoric female adult seemed to escape in a measure its ravages, nursing infants and young children were frequent sufferers. The men would often continue their usual avocations ignorant of their trouble, and many cases of this ambulatory type were observed when these natives applied for treatment at the army hospital of the troops stationed there. Then a careful examination of the patient and a more thorough investigation of the surroundings would reveal a condition of insanitation almost too horrible to be believed, except as one saw it laid before him. The evacuations from the body were deposited in the stream or at the side of the well from which the family water supply was procured; the clothes of a person infected were washed at or near these sources of water supply, and in several instances the corpse of one who had died of the disease was washed so close to the well that the water used ran back into it. Another and a prominent cause was the ingestion of shellfish, mussels, and the like, which the great craving of the Malay blood for animal food compels them to seek, though their usual food is rice boiled in an earthenware jar, and a handful of dried fish with a small quantity of salt. The shellfish and mussels are procured from the contaminated beds in streams into which the filth of the villages and towns has been poured, and the trenches leading from beneath the houses also often furnish a place from which the mussels are secured. These two causes, *viz.*, the ingestion of polluted water and food, together with the chance of the absorption of the germ taking place where no attempt is made at cleanliness in cooking food, or in keeping the utensils clean, are the ones to be considered, rather than any climatological or telluric influence in the propagation and spread of typhoid fever in the Philippines.

The history of the one town in this matter is the same for all in these islands. The white troops in this town and a company of native troops, about two or three hundred at a time, never less than two and sometimes over three hundred, did not have a single case of typhoid fever among them, though the disease raged in the town a short distance away. The precautions were simple and were observed religiously. No water was drunk or used for washing the utensils of the kitchen or mess outfits that was not thoroughly boiled. The food and the preparation of the food, the kitchens, and all receptacles in which food or water was kept, were inspected every day by the surgeon. The latrines, placed at proper distance from the quarters occupied by the troops, were properly disinfected with fresh earth, and the contents were buried carefully.

Cases of typhoid fever were sent into the hospital at this town from detachments in towns ten and twenty miles away, but no case appeared among the troops stationed permanently there. Twelve cases were received from a command across the lake about eighteen miles, and all were traced to the fact that the water used for drinking purposes was procured from a river below a native village, and in which village typhoid fever was raging, the water so used not being properly boiled.

Close observation of these cases of typhoid fever showed but little difference in the essential points to the course run in the United States of the same disease. A careful differential diagnosis was necessary to distinguish it from tropical dysentery and the various forms of malarial fevers so prevalent in many portions of the islands, and also from dengue, which in its early stages is often mistaken for typhoid and may even coexist with it. Being a disease which the nonresident of the tropics is nearly always attacked by during the period when acclimatization is going on (although a most contagious disease, dengue does not receive the attention it should in the way of proper isolation), its presence renders the diagnosis of typhoid difficult at an early stage. Without a resort to Widal's test a positive diagnosis is not made readily during the first week; in fact, any made in less time was open to suspicion. Two forms of fever were here met with. One was the primary fever, due to the infection the typhoid germs produced throughout the system, and the other appeared as the disease progressed, and the brown tongue, dry and beefy in appearance, the delirium changing from a mild, listless form to an

active and often violent type, indicating septicemia. This was often met with here and at other places in the islands, and was especially prone to occur in a climate in which every mucous membrane seems to be congested. This is seen also in the profuse epistaxis and intestinal hemorrhage, so much more frequent in cases of typhoid fever in the tropics than in the colder regions of the temperate zone.

The forms of treatment varied to suit the time and place, but were essentially simple. Absolute rest in bed was enjoined for four weeks at least, even though some cases made a recovery, as far as could be judged, in two or three weeks under the simple but ironclad rules. During the first week, from necessity, some patients were permitted to use the commode rather than the bedpan, and no ill results seemed to follow, but this was positively interdicted afterwards. The wards were cool and well ventilated, this being rendered possible from the construction of the native houses used for hospital purposes. The pulse rate and temperature showed nothing remarkable. The thermometer was placed in the axilla by preference, care being taken to keep this part thoroughly dry at the time.

Even when no hyperpyrexia was noted the patiet received a bath twice a day. This was given either plain, or with vinegar in the water, or salt, alcohol, or alcohol alone. In cases where hyperpyrexia was present the spine was rubbed with salt and whiskey mixed up thoroughly, and this was continued for half an hour and repeated at four-hour intervals after a bath of cold water or the wet-pack. In the early stage of the disease the patient was placed in a large tub, if there was not too great depression of the heart's action. When too great exhaustion was noted the patient was rubbed well with alcohol, parts of the body and limbs being gone over alternately and then the body rubbed all over, especially the back, with olive oil. But little medicine was used, beyond an early dose of calomel, followed by a dose of Rochelle salts in teaspoonful doses every day, its effects being carefully watched. On the eighth or ninth day calomel was again given in small doses for about twenty-four hours, or even gr. vi three times a day for two days for the purpose of eliminating the poison from the intestines and also to antagonize it.

Opium and bismuth controlled the action of the bowels whenever there was a tendency to overaction, while enemas of starch, or opium and water or salt and water, were used, especially if hemorrhage from the bowels was observed. The hypodermic use of morphine, gr. ¼, and of a solution of ergot in 30 minim doses, also hypodermically, every four hours, gave very satisfactory results in such conditions, and the ergot seemed also to exert a quieting influence on the nervous conditions when given alone, quieting and relieving the delirium. The tympanites was relieved by enemas of olive oil, ʒ iv, with turpentine, ʒ i, and carbonate of guaiacol, gr. vi, together with the application of hot turpentine stupes to the abdomen. Alcohol was not given internally in the early stages, and its use was guided by the pulse rate, a dry, brown tongue, and tremor and other symptoms with increase of delirium being indications for its use. In the course of twenty-four hours ʒ iv to ʒ xvi, given in water in ʒ ii doses was usually deemed sufficient. Much good resulted from the administration of aromatic spirits of ammonia ʒ i in water every three hours, especially during a weak spell or preceding or following some slight exertion, such as the bath or the use of the bedpan entailed. The delirium, if every active, was controlled by some form of opium, as morphine or Dover's powder.

The diet of the patient was of the most modified form. As cow's milk was not to be had, malted milk was used as a substitute; a gruel also was made from hardtack, the hard bread issued to the troops, ground fine, with the addition of water and a small quantity of condensed milk. Beef extract, mutton and chicken broths when no overaction of the bowels was observed, and albumen in shape of whites of eggs given in water formed the diet in the early stages of the disease. To this could be added rice water, made by boiling rice carefully and then straining and adding the whites of eggs and stirring the whole up carefully. Food of this character was administered to the patient in quantities of from ʒ ii to ʒ iv every three hours, increasing in quantity about the end of the second week; and as the fourth week passed there were added soft toast, tea without milk, chocolate not too sweet, and eggs, poached or soft-boiled, the quantities being carefully graded by the powers of assimilation and by the condition of the bowels. Solid food was withheld for some time, and as soon as the patient was able to bear transportation safely, transfer was made to the United States, where the bracing air of a northern winter was necessary to complete recovery.

## PHYSICIANS IN FICTION:

### PHYSICIANS AS SEEN BY OLIVER WENDELL HOLMES.

By C. D. SPIVAK, M.D.,

DENVER, COLO.

Many years after he carried all the prizes in sight for original investigations in medical subjects; after twenty years of continuous teaching of anatomy; at a time when he had earned a national reputation as a philosopher, essayist, and wit, and shared international renown with Lowell, Whittier, and Longfellow, when he had reached the mature age of half a century, Dr. Oliver Wendell Holmes wrote his first novel. This is a unique instance in literature of deferred development of talent, and probably is the only precedent which another great physician, Dr. S. Weir Mitchell, followed with such marked success. Dr. Holmes wrote three novels: "Elsie Venner, a Romance of Destiny," originally called "The Professor's Story," in 1860; seven years later appeared "The Guardian Angel"; and again, twenty years later, at the age of seventy-six years, he penned his last novel, "A Mortal Antipathy." Each of these books is remarkable. Each presents a case from a medicopsychological standpoint. We are not concerned here with the literary aspect of the novels, their genre, their romantic elements, delineation of the secondary characters, or the denouement. We will, however, say a few words about the plot of the novels, since this will assist us in the understanding of the problems presented in these fiction-cases, and the better appreciation of the medical types.

Notwithstanding the fact that Dr. Holmes never missed an opportunity of condemning the work and method of one of the greatest novelists of the last century, Emile Zola, yet the problems that occupied the minds of these two men, so different in their temperaments, their style, and their literary armamentarium, were identical. Both set before themselves the task of solving the problem of prenatal and hereditary influences upon the individual. Both wrote what is called the "novel with a purpose."

The key to all of Dr. Holmes' novels is found in a letter of Mr. Langdon, a medical student temporarily engaged as tutor in the Apollinean Institute, addressed to his professor, in which he asks the following questions:

"Is there any evidence that human beings can be

infected or wrought upon by poisons, or otherwise, so that they shall manifest any of the peculiarities belonging to beings of a lower nature? Can such peculiarities be transmitted by inheritance? Have you any personal experience as to the power of fascination said to be exercised by certain animals? Do you think there may be predispositions inherited or ingrafted, but at any rate constitutional, which shall take out certain apparently voluntary determinations from the control of the will, and leave them as free from moral responsibility as the instincts of the lower animals? Do you think there may be a crime which is not a sin?"

*Elsie Venner.*—In this tale, Elsie Venner is the only child of Dudley Venner, whose wife died in giving birth to their daughter. A short while before that happened, the young wife had been bitten by a crotalus, a rattlesnake, and the child was partially endowed with a serpent nature from the moment of her birth. Her eyes were like two glittering diamonds, there was a repellant fascination in them, and she exercised a peculiar influence over all who came in contact with her. She neither laughs, nor cries. She can hate, but she cannot love. She is absolutely uncontrollable. She goes and comes and does as she pleases. She is a menace and danger to all that surround her. The author wishes by this novel to test the doctrine of "original sin" and human responsibility for the disordered volition. In this novel, Dr. Holmes foreshadowed the working out of the next problem, or preparations for the next novel. He says: "If, on presentation of the evidence (in the case of Elsie Venner), she becomes by the verdict of the human conscience a proper object of divine pity and not of divine wrath . . . wherein lies the difference between her position at the bar of judgment, human or divine, and that of the unfortunate victim who received a moral poison from a remote ancestor before he drew his first breath."

Dr. Holmes took up this problem in his second novel, "The Guardian Angel." Myrtle Hazard, at the period of puberty, manifests traits of many of her ancestors, of her great grandmother, who was an Indian; of a grandmother who was "burned by ye bloudy Papists"; of another who died at the stake for witchcraft, etc. "The instincts and qualities belonging to the ancestral traits which predominated in the conflict of mingled lives, lay in this child in embryo, waiting to come to maturity. It was as when several grafts bearing fruit that ripens at different times, are growing upon the same stock. Her earlier impulses may have been derived directly from her father and mother, but all the ancestors who have been mentioned, and more or less obscurely many others, came uppermost in their time, before the absolute and total result of their several forces had found its equilibrium in the character by which she was to be known as an individual. These inherited influences were, therefore, many, conflicting, some of them dangerous. The world of the Flesh and the Devil held mortgages on her life before its deed was put in her hands; but sweet and gracious influences were also born with her."

From the study of the etiology and course of such a case, the author makes the following acute deductions: "It is by no means certain that our individual personality is the single inhabitant of these our corporal frames. . . . Some at least, who have been dead, may enjoy a kind of secondary and imperfect, yet self-conscious life, in these bodily tenements which we are in the habit of considering exclusively our own. . . . This body in which we journey across the isthmus between the two oceans is not a private carriage, but an omnibus."

The third novel, "A Mortal Antipathy" the last of the series, treats of the influence on a man's afterlife, of a severe shock received in early childhood. This time it is a man, Maurice Kirkwood, who, when an infant, was taken suddenly from his nurse's arms by a grown girl, his cousin, and throwing himself from her arms, he fell over the parapet of the balcony on which they were standing. This accident affected the nerves of the child so profoundly that he grew up with a "mortal antipathy" towards womankind in general, and especially towards women at that time of life when they should naturally prove most attractive to the opposite sex. Although Kirkwood makes all kinds of efforts to conquer this psychosis, it is all in vain. Whenever he is brought in the presence of a young woman, there comes over him a sudden faintness, a smothering sensation that threatens to destroy his life. He is doomed to lead a miserable solitary life, avoiding the society of men and women, while the natural social sympathies cry out in revolt.

These are, in short, the themes of the three novels.

It is natural that the unfortunate heroes of these novels should receive treatment from, and remain under observation of, the local physicians. Accordingly, we make the acquaintance of three general practitioners, and a retired physician, the father of one of the three. Although the physicians play but a secondary rôle in the novels, yet the psychological problems involved in the plots and incidents are brought out more boldly and clearly through their words and actions.

Before obtaining a private audience with each of the practitioners, it behooves us to say that the scenes of the three novels are laid in small towns or villages in New England. We have to deal all along with country doctors. None of them is burdened with too much academic learning; the latest fad never reaches them, and the latest discovery comes to them only after it has stood the fire of scrutiny. They don't read overly much. They possess, however, something that no books or laboratories can furnish, and that is: a capacity for work, a willingness to be helpful, broad sympathies, and common sense. It is remarkable that Dr. Holmes, a graduate of Harvard, a student in the best European universities, a college professor for over thirty years in his *alma mater*, a man who passed all his days in Boston, "the hub of the universe," has after all, chosen as types of the true healers, the poor country practitioners. And how well he knew their difficulties and struggles, both physical and intellectual! Here is a graphic description of the daily routine of a country physician:

"Half a dollar a visit—drive, drive, drive, all day—get up at night and harness your own horse—drive again ten miles in a snowstorm—shake powders out of a vial (pulv. glycyrrhizæ, pulv. acaciæ, āa, partes equales)—drive back again, if you don't happen to be stuck in a drift—no home, no peace, no continuous meals, no unbroken sleep, no Sunday, no holiday, no social intercourse, but eternal jog, jog, jog in a sulky, until you feel like the mummy of an Indian, who had been buried in the sitting posture, and was dug up a hundred years afterward."

Here is another of Holmes' fine characterizations: "If that primitive physician, Chiron, M.D., appears as Centaur, as we look at him through the lapse of thirty centuries, the modern country doctor, if he could be seen about thirty miles off, could not be distinguished from a wheel animalcule. He inhabits a wheel carriage. He thinks of stationary dwellings as Long Tom Coffin did of land in general; a house may be well enough for temporary incidental pur-

poses, but for a "stiddy" residence give him a "kerridge." If he is classified in the Linnæan scale, he must be set down thus: *genus homo;* species *Rotifer infusorius*—the wheel animal of infusions."

Let me introduce to you the physician of Elsie Venner, Dr. Kittredge, who, during one of her paroxyms "stood looking at her still, steady, thoughtfully, and tenderly." He is the leading physician in Rockland, a shrewd old man, "who looked pretty keenly into his patients through his spectacles, and pretty widely at men and women and things in general over them. Sixty-three years old—just the year of the grand climacteric. A bald crown, as every doctor should have. A consulting practitioner's mouth: that is, movable round the corners, while the case is under examination, but both corners well drawn down and kept so when the final opinion is made up."

In the following conversation with Langdon, the medical student, will be found a few of Dr. Kittredge's observations: "Why, no," said the old doctor, "I haven't got a great many printed books, and what I have, I do not read quite as often as I might, I'm afraid. . . . When a man that's once started right, lives among sick folks for five and thirty years, as I've done, if he has not got a library of five and thirty volumes bound up in his head at the end of that time, he'd better stop driving round and sell his horse and sulky. I know the bigger part of the families within a dozen miles' ride. I know the families that have a way of living through everything, and I know the other set that have the trick of dying without any kind of reason for it. I know the years when the fevers are in earnest, and when they are only making believe. I know the folks that think they are dying as soon as they are sick, and the folks that never find out they are sick until they are dead. You can't tell a horse by driving him once, Mr. Langdon, nor a patient by talking half an hour with him."

Dr. Holmes takes a great deal of delight in the way Dr. Kittredge behaved at the bedside. He always came into the sickroom with a quiet, cheerful look, as if he had a consciousness that he was bringing some sure relief with him. "The way a patient snatches his first look at his doctor's face, to see whether he is doomed, whether he is reprieved, whether he is unconditionally pardoned, has really something terrible about it. It is only to be met by an imperturbable mask of serenity, proof against anything and everything in a patient's aspect."

Another trait of Dr. Kittredge is a desideratum even in our days: "Some very silly people thought the old doctor did not believe in medicine. . . . Sometimes he lost a family of the more boorish sort, because they did not think they got their money's worth out of him, unless they had something more than a taste of everything he carried in his saddle bag."

That Dr. Kittredge is capable of making a snap diagnosis under trying circumstances, is illustrated by the following episode:

At a social entertainment given by Colonel Sprawle, the following takes place:

A sound something between a howl and an oath startled the company. . . . "He's chokin', he's chokin'," was the first exclamation. "Slap him on his back."

"He's black in the face," said widow Leech, "he's swallowed something the wrong way. Where's the doctor? Let the doctor get to him, can't ye?"

"If you will move, my good lady, perhaps I can," said Dr. Kittredge, in a calm tone of voice. "He's not choking, my friends," the doctor added immediately he got sight of him.

"It's apoplexy—I told you so—don't you see how red he is in the face," said old Mrs. Peake, a famous woman for "nussin'" sick folk, determined to be a little ahead of the doctor.

"It's not apoplexy," said Dr. Kittredge.

"What is it, doctor? What is it? Will he die? Is he dead? Here is his poor wife, the widow Soper, that is to be, if she ain't already."

"Do be quiet, my good woman," said Dr. Kittredge—"Nothing serious, I think, Mrs. Soper. Deacon!"

At the doctor's sharp appeal, the deacon lifted his head.

"It's all right," said the doctor as soon as he saw his face. "The deacon had a smart attack of neuralgic pain, that's all."

The doctor kept his countenance, but his diaphragm was shaking the change in his waistcoat pocket with subterranean laughter. He had looked through the spectacles and seen at once what had happened. The deacon, not being in the habit of taking his nourishment in the congealed state, had treated the ice cream as a pudding of a rare species, and to make sure of doing himself justice in its distribution had taken a large mouthful of it without the least precaution. The consequence was a sensation as if a dentist were killing the nerves of twenty-five teeth at once with hot irons, or cold ones, which would hurt rather worse.

When Dr. Kittredge wishes, for some reason, to keep a thing to himself, he does it gracefully. A Mr. Pekham wishes to pump him as to whether there is any "ketchin' complain' goin' about in the village." Dr. Kittredge, without a moment's hesitation makes answer:

"Well, yes, I should say there was something of that sort—measles, mumps, and sin—that is always catching."

In "The Guardian Angel" we meet with Drs. Hurlbut, father and son. "Old Dr. Lemuel Hurlbut, at the age of ninety-two, very deaf, very nearly blind, very feeble, liable to lapses of memory, was yet a wise counsellor in doubtful and difficult cases, and on rare occasions was still called upon to exercise his old skill." Dr. Holmes makes an observation concerning a nonogenarian, which bears quoting: "A man over ninety is a great comfort to all his elderly neighbors, he is a picket guard at the extreme outpost, and the young folk of sixty and seventy feel that the enemy must get by him before he can come near their camps."

Although under the treatment of Dr. Fordyce Hurlbut, the son, yet the case of Myrtle Hazard was of such a nature that it was deemed advisable to call in consultation, Dr. Hurlbut, Senior.

"Myrtle Hazard, father, had a narrow escape from drowning, and it has left her in a rather nervous state. You remember Myrtle Hazard? She is the great-granddaughter of your old friend the deacon." After a silent moment: "Myrtle Hazard, Myrtle Hazard. Yes, yes, to be sure. The old Withers stock, good constitution, a little apt to be nervous, one or two of 'em. I've given 'em a good deal of valerian and assafetida—not quite so much since the new blood came in. There ain't the change in folks, people think—same thing over and over again. I've seen six fingers on a child that had a six-fingered great-uncle, and I have seen that child's grandchild born with six fingers. Does this girl like to have her own way pretty well, like the rest of the family?"

After the consultation the doctors left the room to talk it over. "It does not amount to much, I suppose, father," said Dr. Fordyce Hurlbut. "You made the pulse about ninety—a little hard—didn't

you, as I did? Rest, and low diet for a day or two, and all will be right, won't it?"

Was it the feeling of sympathy, or was it the pride of superior sagacity that changed the look of the man's wrinkled features? "Not so fast—not so fast, Fordyce," he said. "I've seen that look on another face of the same blood—it's a great many years ago, and she was dead before you were born, my boy, but I've seen that look and it meant trouble then, and I am afraid it means trouble now. I see some danger of a brain fever, and if it does not have that, then look out for some hysteric fits, that will make mischief. I've been though it all before, in that same house. Live folks are only dead folks warmed over. I can see 'em all in the girl's face—handsome Judith to begin with. And the queer woman, the Deacon's mother—there's where she gets that hysteric look. Yes, and the black-eyed woman with the Indian blood in her—look out for that—look out for that."

"Four generations—four generations, man and wife—yes, five generations, before this Hazard child I've looked on with these eyes, and it seems to me I can see something of almost everyone of 'em in this child's face—it is the forehead of this one, and it's the eyes of that one, and it's that other's mouth, and the look that I remember in another, and when she speaks, why, I've heard that same voice before—yes, yes—as long ago as when I was first married."

We will now learn something about Fordyce Hurlbut, her regular attending physician. He was a widower, not yet forty years old, a man of a fine masculine aspect and a vigorous nature. He was a favorite with his female patients, perhaps many of them would have said because he was good looking, and pleasant in manners, but some thought in virtue of a special magnetic power to which certain temperaments were impressible.

At one of his visits to Myrtle Hazard, he found the nurse unusually agitated, and as soon as he could get her out of the house she made the following oration:

"She's been attacked, doctor, sence you been here, dreadful. It's them high stirricks, doctor, 'n I never seen 'em higher, nor more of them. Laughin' as if she would bust. Cryin' as if she's lost all her friends, 'n was follerin' their corpse to their graves. And spassums, sech spassums! And ketchin' at her throat, 'n' savin' there was a great ball a risin' unto it from her stomick. One time she had a kind o' lockjaw like. And one time she stretched herself out 'n' laid just as still as if she was dead. And she says now that her head feels as ef a nail had been driv' into it—into the left temple, she says, and that's what makes her distressed now."

Dr. Fordyce returned to the bedside, and asked, "Where is your uneasiness, Myrtle?" She moved her hand slowly and passed it on her left temple. He laid his hand on the same spot, kept it there a moment and then removed it. She took it gently with her own, and placed it on her temple again. As he sat watching her, he saw that her features were growing easier, and in a short time her deep, even breathing showed that she was asleep.

"It beats all," the old nurse said. "Why, she's been a complainin' ever since daylight, and she hain't slep' not a wink afore sence twelve o'clock las' night. It's jes' like them magnetizers. And she lays there jest as peaceful as a new-born babe—that is accordin' to the sayin' about 'em, fer as to peaceful new-born babes, I never see one that come t' anything that did no' screech as ef the haouse was afire, 'n 't wanted to call all the fire engines within ten miles."

Dr. Fordyce thought that the tranquilizing effect of the contact of his hand was a mere coincidence. At the next visit all the strange spasmodic movements, the choking, the odd sounds, the wild talk, the laughing and crying were in full blast. All the remedies had been of no avail. The doctor could not refuse his quasimagnetic influence, and placed the tip of his fingers on her forehead. The result was the same as the day before—the storm was soon calmed, and she fell into a quiet sleep.

Every day after that matters became worse. Myrtle Hazard now seemed to have lost the healthy instinct for veracity and honesty. She feigned all sorts of odd symptoms, and showed a wonderful degree of cunning. The nurse describes the situation to Mr. Byles Gridley in the following way:

"Sech doin's, sech doin's! The gal is jest as much bewitched as ever any gal was sence them that was possessed in scriptur! Ef that doctor don't stop comin', she won't breathe without his helpin' her to, before long. And, Mr. Gridley, I don't like to say so, but I can't help thinkin' he's gettin' bewitched too. Man is man and gals is gals. I wouldn't trust no man, not if he was much under a hundred years old,—and as for a girl—! . . ."

Mr. Gridley, a scholar, some sixty years old and a bachelor, took a great deal of interest in the young folks at Oxbow village, illustrating thereby that singular law laid down by old Dr. Hurlbut, namely, that "at a certain period of life, say from fifty to sixty and upwards, the grandpaternal awakens in bachelors, the rhythm of nature reaching them in spite of their defeated intentions; so that when men marry late, they love their autumn child with a twofold affection, father's and grandfather's both in one." After his conversation with the nurse, he called Dr. Fordyce Hurlbut to his study, engaged him in a talk about old medical prints and folios, and then asked him whether he had read the oath of Hippocrates. Dr. Fordyce said that he had read it, but did not remember it.

"It's worth reading, doctor, it's worth remembering, and old as it is, it is just as good to-day as it was when it was laid down as a rule of conduct four hundred years before the Sermon on the Mount was delivered. Let me read it to you, Dr. Hurlbut: 'My life shall be pure and holy, into whatever house I enter, I will go for the good of the patient; I will abstain from inflicting any voluntary injury, and from leading away any, whether man or woman, bond or free." The doctor took the hint. It is not necessary to quote further the conversation. True to his honorable calling and his truthful character, he admitted the peculiar relations into which he was daily drawn, and under a pretext left Oxbow.

There remains one more physician whose hand we are to shake. It is Dr. Butts, who treats Maurice Kirkwood, the hero of "A Mortal Antipathy." Dr. Butts was the leading medical practitioner, not only of Arrowhead village, but of all the surrounding regions. He was an excellent specimen of the country physician, self reliant, self sacrificing. "He had that sagacity without which learning is a mere encumbrance, and he had also a fair share of that learning, without which sagacity is like a traveler with a good horse, but who cannot read the directions on the guide boards." He was not a man to be taken in by names. He knew too well that what is spoken lightly of as a "nervous disturbance" may imply that the whole machinery of life is in a deranged condition, and that every individual organ would groan aloud if it had any other language than the terrible inarticulate one of pain, by which to communicate with the consciousness.

It is natural that the inhabitants of Arrowhead should become intensely interested in Maurice Kirkwood, the solitary and mysterious visitor. Dr. Butts

finds out from the servant of Kirkwood, an Italian, that his master has "una antipatia." He did not smile and say to himself that this was an idle whim, a foolish fancy which the young man had got into his head. . . . He was prepared to believe in some exceptional, perhaps, anomalous form of exaggerated sensibility. At this juncture I must introduce to you Dr. Butts' wife, the only doctor's wife in the three novels.

"Dr. Butts carried these questions home with him. His wife was a discreet woman, whom he could trust with many professional secrets. He told her of Paolo's, the servant's, revelations, and talked it over with her in the light of his experience and her own; for she had known some curious cases of constitutional likes and dislikes.

"Mrs. Butts buried the information in the grave of her memory, where it lay for nearly a week. At the end of this time, it emerged in a confidential whisper to her favorite sister-in-law, a perfectly safe person. Twenty-four hours later, the story was all over the village that Maurice Kirkwood was the subject of a strange, mysterious, unheard-of antipathy to something—nobody knew what, and the whole neighborhood resolved itself into an unorganized committee of investigation." Dr. Butts, "if he suspected the channel through which it had reached the little community, he did not see fit to make out of his suspicion a domestic casus belli." He had to concede, however, "that the worthy lady had forgotten the rule, that doctor's patients must put their tongues out, and a doctor's wife must keep her tongue in."

In reviewing the characteristics of the four physicians in the novels of Dr. Holmes, we find that they do not represent four distinct types. There is not a single feature by which they can be distinguished one from another, except their names. They are all leading physicians in their respective communities, they are honest, hard working, and endowed with a great deal of common sense. We recognize in Dr. Kittredge all the traits of Dr. Butts and the old Hurlbut, and *vice versa*. They are lovable characters, no doubt, and one wishes that in time of sickness he may have the good fortune of being treated by one of these elderly physicians. But they lack the stuff that produces heroic personalities like those in the Country Doctor of Balzac, Dr. Pascal of Emile Zola, or even the unpretentious doctor of the old school of Maclaren. Granted that the physicians in Holmes' novels were never intended to be heroes, they are secondary personages, and were merely introduced to give the novels a scientific coloring. Yet, the fact remains that all these secondary characters are almost identical, even to the propensity of holding lengthy theological discourses with ministers—which from an artistic standpoint is rather monotonous.

It is a pity that a man of Holmes' versatility and practical temperament did not create a type of a physician more worthy of his genius and of his profession.

---

**Peroneal Resection as a Means of Correction in Rigid Valgus.**—The management of three classes of valgus is considered by Charles F. Painter as follows: (1) Feet whose function is impaired through inability to allow inversion at the mediotarsal joint, this being due to intertarsal sensitiveness causing reflex spasmodic resistance. If overcorrection is not possible, an anesthetic should be given and the adhesions broken up if they exist; if they do not, and after complete anesthesia has brought about muscular relaxation there is no resistance to force, the case probably belongs to a type of valgus in which spasdomic contracture of the peroneals is responsible. (2) The peroneal, in which attempts to correct the pronation and abduction are accompanied by a tautness of the peroneals. Under ether the spasm of these cases disappear, and if there is no intertarsal adhesions the case is probably one of pure peroneal spasm, and should be treated by resection of the peroneals and not by simple manipulation. (3) Bony deformity. The inner border of the foot is lengthened; manipulation and peroneal resection alone are of no avail in this condition, and the restitution of the arch and functional improvement is to be obtained only by the removal of the scaphoid. This shortens the inner border and removes the wedge which prevents correction of abduction. Sometimes peroneal resection may be required. The technique of the operation is as follows: The peroneals are exposed above the external maleolus. The peroneus longus is the first to come in view, and is wholly tendinous in this situation; the peroneus brevis beneath it is both muscular and tendinous. From three-fourths to one inch of both tendons are resected and the sheath destroyed. This latter is necessary to insure the permanency of the result. The foot is then forcibly overcorrected after closing the wound, and is retained in an overcorrected position by a plaster-of-paris bandage. It is left in this position for two or three weeks. At the end of this time the plasters may be removed and high Thomas heels applied, the patient being allowed the use of the feet.—*Boston Medical and Surgical Journal.*

**Multiple Primary Carcinomata.**—Richter adds five cases to this group. Three distinct esophageal tumors were present in each of the first two cases. As the intervening mucosa was apparently normal, the writer holds the tumors to have developed independently of one another. He admits, however, the possibility of transplantation of tumor cells through the submucous lymphspaces, or of secondary involvement of the esophageal wall through an adherent lymphnode containing a metastasis. An instance of the former mode of transmission could be demonstrated in the mucosa between two of the tumors in one of the cited cases. Richter further reports the following cases in which the independent origin of the neoplasms hardly admits of question: 1. Adenocarcinoma of the thyroid with epithelial carcinoma of the uterine cervix. Metastases corresponding to both types of carcinoma were found in the lungs. The regional lymphnodes contained metastases corresponding to the type of tumor in the region drained. 2. Adenocarcinoma of the breast; epithelial carcinoma of the uterus. The tumors formed independent metastases in the liver. Metastases in the axillary nodes were adenomatous in type; those in the inguinal nodes consisted of pavement cells with epithelial pearls. 3. Malignant papillary cystoma of the ovary; adenocarcinoma of the sigmoid flexure. The lymphnodes of the mesentery of the sigmoid contained metastases corresponding to the intestinal tumor.—*Wiener klinische Wochenschrift.*

**Eye Affections Dependent Upon Diseases of the Teeth.**—Hugh Blake Williams draws our attention to affections of the teeth as the cause of various eye troubles, some of them of considerable severity. The distribution of the fifth nerve and the proximity of the superior maxillary bone to the orbit, and the continuance of the periosteum of the orbit with that of the alveolar process, with the course of the angular artery and certain veins, indicate to us the means by which the morbific influence is carried. The passage of bacteria from the mouth, by way of the nose, into the conjunctival sac will account for inflammations of the conjunctiva and cornea. Such serious affections as cellulitis and abscess of the orbit, strabismus, ptosis, paresis, and spasm of the eye muscles, have all been traced to the teeth. Alveolar periostitis may extend to the orbit. The author describes cases of blepharospasm, strabismus, insufficiency of the external rectus, and headache which he has had under his care, in which the treatment of carious teeth cause the eye symptoms to disappear.—*The Illinois Medical Bulletin.*

## THE CONTAGIOUSNESS OF ERYSIPELAS.

THE idea that erysipelas is a virulent type of contagious disease has taken such a firm hold on both the lay and professional mind, that even the apparently complete refutations based on advanced bacteriological investigations, have thus far failed to overcome it entirely. The fear of contact with the afflicted one makes the latter an object to be zealously avoided, and if he happens to be an inmate of a hospital ward, immediate and complete isolation is his fate. And yet there may be others present infected with much more virulent types of organisms, who are not considered for a moment any source of danger to the other patients. It is proper to ask why erysipelas is so sharply differentiated from inflammatory processes depending on bacterial infection of a similar kind.

A defect in the epithelial covering of the skin or mucous membrane is quite generally admitted to furnish an entrance for the pathogenic organism which produces erysipelas, and this in itself marks the disease as a wound infection. It also furnishes a sharp contrast to the picture afforded by the course of a typical contagious disease which is disseminated through the air or by an intermediary. Erysipelas has ceased to be the *bête noir* of hospital surgery, but how much of this favorable result is to be ascribed to our more complete knowledge of wound infection and wound treatment, how much to the better training and control of the ward attendants, need not be discussed here. There is no doubt of the fact, however, that reports of erysipelas epidemics have about disappeared from our literature.

A great deal of the mystery surrounding this disease has been cleared up by the observations of recent investigators. These results should be more generally known, in order that patients thus afflicted may be freed from the opprobrium so often attached to them, and which is only satisfied by their complete and to them certainly most annoying, isolation. There is no reason to question the facts obtained by these writers, because they are based on careful bacteriological investigations. The most recent is by Franke of Prof. König's clinic (*Deutsche Zeitschrift für Chirurgie*, Vol. 78, No. 1), who has succeeded in demonstrating that the streptococcus gains entrance through minute and often unnoticed wounds in the skin or mucous membranes, and then continues its growth in the lymphatic channels of the cutis. Erysipelas may, therefore, be defined as a lymphangiomatous disease, and in no instance was it found that the germs returned to the surface of the skin, and were present in either the scales or the bullæ. Whether the streptococcus produces an erysipelas or a cellulitis possibly depends on the size of the wound and the depth to which the organism may have penetrated, and finally, on the virulence of the particular strain. It seems evident, therefore, that the patient is not a source of danger to his surroundings, so long as the surface of his skin remains intact. When he indulges in scratching, however, in order to relieve the intense itching, the corium is likely to be lacerated, and the exuding fluid has been proved to contain the streptococci. In this manner the infectious material may unconsciously be distributed and so, in order to avoid further dissemination of the disease, it is essential that the dispersion of the germs be limited by the application of proper occlusive dressings; when this is properly done the patient need not, as a rule be isolated. The exception deals only with cases in which sufficient dressings for the purpose are impracticable, as in facial, perineal, and some other locations of erysipelas. Here it will be more convenient to isolate the patient until the inflammatory stage has disappeared, but the isolation need not be prolonged beyond this period, as the desquamative stage has been shown to be without danger.

When, then, the diagnosis of erysipelas has been made, Franke contends, one need no longer continue to regard the patient in abject terror. The disease should be viewed in the same light as any other condition depending on wound infection, and treated accordingly.

## ELECTROCUTION.

ALTHOUGH "the chair" has for nearly two decades been the legal mode of execution of criminals in this State it has by no means received the unanimous approval even of those who believe in capital punishment. The statement that death by means of an electric current of high voltage is practically instantaneous and painless has not been accepted by all who have studied the subject or witnessed an electrocution. If muscular contractions and cardiac pulsation are accepted signs of continued life, it is very certain that death is not instantaneous in all cases; and, indeed, in certain instances there has been a strong suspicion that the real executioner was the physician who performed the autopsy after life was assumed to be extinct. Whether the method is painless or not depends upon whether consciousness is at once abolished; and that is a point which is naturally very difficult to determine in the electric chair.

In an article in the *Journal of Mental Pathology*, Vol. VII., No. 2, Dr. Louise Robinovitch describes some experiments on rabbits with an electric current of low tension, from which she draws conclusions very adverse to the legal mode of execution in New York. These experiments were made with the Leduc current of low voltage, only fourteen volts constituting a lethal current in the rabbit, the proportionate voltage in the case of man being, probably, from 150 to 200. The cathode was applied to the forehead and the anode to the abdomen. It was found that consciousness was completely abolished when only about five volts were turned on, this current inducing a condition having every appearance of a deep sleep. About two and one-half times the voltage producing "electric sleep" was

necessary to cause death. There was neither edema, blistering, nor burning of the parts to which the electrodes had been applied.

Pending the abolition of electrocution and of capital punishment in general, of which Dr. Robinovitch is a pronounced opponent, she urges that the process be made as humane as possible by the use of these electric currents of low voltage. By means of them suspension of consciousness is quickly and absolutely secured, and cardiac and respiratory paralysis is rendered certain; at the same time the horrible burning of the parts in contact with the electrodes is avoided. This last, of course, is a purely esthetic argument, but for the sake of the electrocutioner (it would be worth while abolishing this method of killing to get rid of such a word) and of the witnesses the process should be made as little brutalizing as possible. But perhaps the strongest argument in favor of the employment of a current of low voltage, assuming that there was no flaw in these experiments, and that the same certainty of results would obtain in the human body as in the rabbit, is that it surely kills, and the dreadful suspicion that possibly the physician is in the end the real executioner would then be stilled. Resuscitation was attempted in Dr. Robinovitch's experiments, and always failed when radial pulsations or heart beats and muscular movements were not visible or perceptible—but not when these were present. In some of the cases of electrocution in New York there were chest movements and radial pulsations after from one to three contacts; and in one case there was a slight fluttering of the radial pulse even after the final contact was broken, though the writer states that this rapidly ceased. So far as we know, no attempts at resuscitation were made in these cases, so the doubt remains whether life was really extinct.

We are not prepared to agree with Dr. Robinovitch, or with Dr. Castelli, in a recent communication to the MEDICAL RECORD, that capital punishment should be abolished. There is room to doubt its value as a deterrent to crime, and even to question whether the spectacular hangings of former times may not have been an incentive to murder. In eastern Kentucky, it was the fashion, not many years ago, for a condemned murderer to distribute handkerchiefs with his portrait printed on them to all the spectators of the ceremony, as a memento of his taking off, and the event was made the occasion of a holiday for all the neighbors, friends and foes alike. But as a protection to society by removing a dangerous enemy, there is much to be said in favor of the execution of a desperate criminal; for with the pardoning power in the hands of a soft-hearted or weak executive, a sentence of imprisonment for life carries with it no certainty of permanence. As compared with hanging, electrocution, with its partial secrecy, is a preferable method, but it should be carried out in a humane manner, if its object is to rid the State of a dangerous character, and not to inflict punishment on the individual. From this point of view the present method of inflicting capital punishment in New York State cannot be regarded as ideal. Perhaps the substitution of currents of low voltage, as used in the experiments to which we have referred, might make the conditions of execution more tolerable. The subject is at least worthy of further study and experimentation, with a view to the confirmation or rejection of Dr. Robinovitch's conclusions.

## THE SUMMER DIARRHEAS OF INFANCY.

ALTHOUGH the bacillus of dysentery and its congeners have in recent years been found in the intestinal discharges from a considerable proportion of infants suffering from summer diarrhea, it is not contended that this organism is the sole and exclusive cause of the group of disorders mentioned. Moreover, it has seemed possible that often the organisms in question have played the part merely of saprophytes; while at other times, no doubt, they constitute the etiological factor with respect to both anatomical lesions and clinical manifestations. That other factors are operative in the conditions under consideration there is now ample evidence to show.

For the purpose of clearing up a number of moot points in this connection, Dr. Chas. Hunter Dunn (*Archives of Pediatrics*, June, 1905), made a careful study of 620 consecutive cases of diarrhea in infants, observed during the summer months of 1903 and 1904, at the out-patient department of the Thomas Morgan Rotch, Jr., Hospital for Infants. As a result of this investigation, the conclusion is reached that the diarrheal diseases of infancy occurring during the summer months differ in no way, either clinically or anatomically, from similar diseases occurring at other seasons of the year, except in their much greater frequency. In view of the variety of lesions found in cases of similar etiology and similar clinical course, and of the lack of correspondence between the anatomical and the clinical picture, classification on an anatomical basis, as, for example, into functional and organic, or non-inflammatory and inflammatory (ileocolitis), is not convenient from the etiological standpoint. Accordingly, Dr. Dunn proposes the following classification: (1) acute nervous diarrhea, characterized by loose stools of normal color and odor, without abnormal constituents; (2) irritative diarrhea, characterized by the absence of persistent fever and by the presence of curds and undigested masses in the discharges; (3) fermental diarrhea, characterized by the absence of fever and by green stools of a foul odor; (4) infectious diarrhea, characterized by the existence and persistence of fever and by a tendency toward early signs of ileocolitis, as indicated by the presence of blood and excess of mucus in the discharges—infantile dysentery if the bacillus of dysentery is the causative factor; (5) rare cases presenting conditions corresponding to heat exhaustion and cholera infantum.

Of the above-mentioned forms irritative and fermental diarrhea were found to be by far the commonest. In all forms the chief or primary etiological factor is the increased heat of the weather during the summer months, causing functional disturbance of the nervous system or of the digestive apparatus. Bacteria act as a secondary cause in a certain number of cases and particularly of the infectious type of diarrhea. Infection may be brought about through the introduction of bacteria from without or through the activity of bacteria already present in the intestines. The bacillus of dysentery is the cause in most cases of the infectious group. It is often found in cases in which probably it has no causal relation to the morbid process present. Other microorganisms probably act as causative agents in some infectious cases. The anatomical changes of various kind included under the term ileocolitis, may occur in asso-

ciation with any of the types of diarrhea described, except the acute nervous form. Anatomical changes of some kind probably occur in all cases of infectious character.

### A Vaccine for Kala-Azar.

The real nature of tropical splenomegaly, or kala-azar, although the disease has long been known and studied in India and other tropical and subtropical countries, has been recognized only for the past five years, since Leishman discovered the protozoan parasite in the spleen. Since that time the microorganism has been found by Donovan and others in the bone marrow, the liver, the lymph nodes, and on the surface of the intestinal ulcers. Before Leishman, Cunningham had found a protozoan, apparently identical morphologically, in cases of Delhi boil, and more recently Wright has found the same parasite in the Aleppo button. The identity of the parasite in two such unlike conditions was considered singular, but its possible significance was not appreciated until very recently. In a paper read before the Tropical Section of the British Medical Association, in July last, Sir Patrick Manson called attention to the fact, basing upon it a suggestion which may prove to be of great practical value. The distribution of the parasite in kala-azar, he said, is very general, while in oriental sore it is found only locally; yet even in the latter case there is some constitutional effect produced, since the threatened development of the sore in one part can be averted by immediate inoculation with the specific virus in another part. There are, therefore, two constitutional diseases, clinically distinct, produced by the same parasite, or by two very closely related parasites. The suggestion of Manson was that these two diseases might be related in the same way as vaccina and smallpox; and this is supported by the popular belief that oriental sore is acquired from the camel. If such is the case, the analogy need be carried but a step further to secure an efficient vaccine for the dreaded kala-azar. In the paper referred to above, Manson says that "oriental sore may bear the same relation to kala-azar that vaccina does to smallpox; and possibly the virulence of the kala-azar germ has been got rid of during its passage through the camel just as the smallpox germ is deprived of its virulence by passing through the cow. This is conjecture, but seems to be a point worth working out, for should the conjecture turn out to be correct, we may have ready to hand a means of preventing kala-azar."

### Magnesium Treatment of Cavernous Tumors.

A few years ago E. Payr recommended as one of great efficacy a method for removing inoperable cavernous tumors by means of magnesium pencils inserted in the growth. Tollens (*Zeitschrift für Chirurgie*, Vol. 77, Nos. 1 and 3) reports his experience with the method in an angioma of the skin on the arm of a four months' old child. A number of thin magnesium pencils were thrust through a small opening in the skin directly through the tumor and permitted to remain in place. No diminution in the size of the growth could be demonstrated, and as it was, on the contrary, increasing in extent, it was excised four weeks later in several sittings with favorable results. Subsequent examination of the tissues showed that the magnesium produced very little reaction, and in this case, at least, the method must be looked upon as a failure.

## News of the Week.

**The Medical Society of the State of New York.**—The centennial meeting of this society will be held at Albany, January 30–February 1, 1906, under the presidency of Dr. Joseph D. Bryant of this city. The president has appointed as his Business Committee Drs. Leo H. Neuman of Albany, Algernon T. Bristow of Brooklyn, and Herbert U. Williams of Buffalo. Communications regarding the program of this meeting should be addressed to one of the members of this committee. The secretary of the society is Dr. Frederic C. Curtis, 17 Washington Avenue, Albany. The chairman of the Centennial Celebration Committee is Dr. A. Jacobs of this city, the secretary is Dr. George R. Fowler, 301 Dekalb Avenue, Brooklyn.

**The Fifth Annual Conference of Sanitary Officers of the State of New York** will be held in the capitol at Albany, October 4 and 5, 1905, under the presidency of Dr. Eugene H. Porter, State Commissioner of Health. Among other subjects to be discussed will be the local and institutional control of contagious diseases; the pathology of diphtheria; studies of pneumonia, typhoid fever, and cerebrospinal meningitis, and the pollution and purification of public water supplies. Many prominent sanitarians and laboratory workers are expected to be present and to take part in the discussions.

**New Board of Health Laboratories.**—The laboratories of the research bureau of the Board of Health, in East Sixteenth street, have been moved into the new six-story fireproof building about 100 feet northeast of the old stable in which Dr. Park has had his headquarters for years. The new laboratories are equipped with all modern conveniences, including an elevator, and will accommodate seventeen research workers and forty-seven assistants. The first two floors will be devoted to executive offices and dormitories.

**A County's Responsibility for Mad Dog Bites.**—Claims presented recently by two women to the County Commissioners of Hamilton County, Ohio, for expenses incurred through mad dog bites have been allowed by the County Commissioners. The claims are the first to be paid under the recent legislation making a county responsible for medical treatment necessary for rabies. The claims were presented some time ago and the counsel for the County Commissioners made a lengthy investigation as to the county's liability. The claims were for $201 and $191, respectively.

**Diphtheria in Chicago.**—The diphtheria death rate has been greatly decreased of late years. Before the Chicago Health Department undertook the diagnosis for physicians and the distribution of antitoxin for its treatment the average annual death rate from this disease was 13.7 per ten thousand of population. Under this laboratory work the rate has fallen to an average of 4.9. In 1904 it was only 2.04 per ten thousand.

**County Societies Established in Georgia.**—The *Hall County Medical Society* was organized at a meeting held at Gainesville on September 15. The following officers were chosen; *President*, J. W. Bailey; *Vice-President*, J. W. Oslin; *Secretary and Treasurer*, Dr. P. E. B. Robertson; *Censors*, Drs. J. B. Rudolph, W. A. Palmour and J. H. Downey. The *Stephens County Medical Society* was organized at Toccoa on September 18. The following officers were elected: *President*, Dr. Jeff Davis; *Vice-President*, Dr. W. L. McBath; *Secretary and Treasurer*, Dr. J. H. Crawford; *Censors*, Drs. Claude J. Verner J. H. Edge, and W. H. Parker. The

organizer of both societies was Dr. W. B. Hardman of Commerce, Ga.

**Tuberculosis Clinics in Cleveland.**—Dr. Friedrich, health officer of Cleveland, O., has decided to establish a free clinic in that city for the treatment of tuberculosis on the fat-and-vegetable-juice plan. The scheme has met with considerable opposition from some of the local practitioners who do not regard the value of the system sufficiently established to warrant such a quasi official indorsement.

**A Hospital Threatened.**—A wealthy property owner of Palo Alto, Cal., is reported to have threatened to bring legal proceedings against the Students' Guild, of the Stanford University to have their hospital removed from within the city limits, on the ground that it is a menace to the health of the community and consequently causes a deterioration in the price of property. As the hospital was built at a cost of $5,000 and has already proved a great benefit to many students during illness, efforts are being made to appease the angry one. An offer to receive the citizens of Palo Alto on the same terms as the students is said to have failed to exert any mollifying influence.

**Yellow Fever.**—According to the official reports, Pensacola, Fla., is now in a worse plight than New Orleans. For the twenty-four hours ended at 6 P. M., Monday, there were twenty-five new cases, scattered all over the city. In New Orleans the daily average of new cases is about thirty. The total number of cases reported up to Wednesday was 2,918, and of deaths 380. A comparison of the figures shown by the records of the fever epidemic of 1878 with the figures of this year shows most favorably for 1905. There had been 6,926 cases of yellow fever reported up to September 17, 1878, with 2,176 deaths, making the death rate 31.4 per cent. Up to the same date this year the total cases were 2,571 and the deaths 335, making the death rate 13 per cent. The fever started about the same time in both years, and the difference in cases in favor of this year is due to the modern methods of fighting the disease.

**The Cholera.**—A case of this disease has occurred in Berlin in the person of a bargeman on a coal boat in the Spree, in the heart of the city. Up to noon on Monday last the total number of cases in Germany was 246, and of deaths 85.

**Dr. George F. Butler** has tendered his resignation to the College of Physicians and Surgeons of Chicago, where for nearly twelve years he has held the chair of Materia Medica, Therapeutics, and Clinical Medicine.

**Dr. H. L. Barnes** of Brooklyn, formerly assistant to Dr. King of the Loomis Sanatorium, will, it is believed, be appointed medical superintendent of the Rhode Island State Sanatorium for the treatment of tuberculosis.

**Dr. Claude A. Smith** has been appointed city bacteriologist and chemist to the board of Health of Atlanta, vice Dr. H. F. Harris who resigned to accept the position of secretary to the State Board of Health.

**Dr. Don D. Grout** of Waterbury, Vt., has been appointed superintendent of the Vermont State Hospital for the Insane. Dr. Grout was born in 1849 and is a graduate of the Medical Department of the University of Vermont in 1872.

**The Sixth International Congress of Psychiatry** will be held at Geneva in 1909 under the presidency of Dr. Th. Flournoy. The American members of the international committee of propaganda are Drs. Strong, Cattell, Baldwin, Ladd, Munsterberg, Stewart, Stanley Hall, and Titchener. The secretary of the congress will be Dr. E. Claparede of Geneva.

**Laboratory for the Army Hospital at Presidio.**—Contracts have been awarded for the building of a laboratory in connection with the army general hospital at Presidio, San Francisco, at a cost of $10,000.

**Bequest to the Wistar Institute.**—The Wistar Institute of Anatomy and Biology at the University of Pennsylvania, by the will of its recently deceased founder, Gen. Isaac J. Wistar, is to receive the greater part of his $2,000,000 estate, and also his right arm and brain to aid the cause of anatomical research. That part of the will which bequeaths the arm and brain reads as follows: "I bequeath to the Wistar Institute of Anatomy and Biology my right arm, said to be a desirable specimen of gunshot ankylosis, and also my brain, to be removed by said institute promptly after my death."

**Dismissal of a Bellevue Interne.**—One of the internes at the Bellevue Hospital house staff has been dismissed on charges of insubordination. One of the allegations is that he threw electric light bulbs out of the window, and on being taken to task for this he denied the charge in so emphatic a manner as to lead to his enforced resignation.

**Newspaper Medicine.**—According to the daily press many new things have been learned about heart action by two investigators at the University of Chicago, and one of them is quoted as having said that "What we have learned gives us hope that some day we may replace the wounded or worn out heart of a human being with the healthy, youthful, and strong one from a living monkey."

**Japan's Total Losses in the War.**—It is stated that Japan's war losses so far have been 46,180 killed, 10,970 deaths of injuries and 15,300 deaths from sickness. The loss of life from illness has been less than a quarter of the total number of deaths, which is 72,450.

**Diphtheria at Annapolis.**—An outbreak of diphtheria has developed among the members of the new fourth class at the Naval Academy and ten cases have been reported. A strict quarantine has been instituted.

**Dr. William Osler,** formerly one of the medical faculty of Johns Hopkins University and now Regius Professor of Medicine at Oxford, England, has accepted the post of Thomas Young Lecturer on Medicine at St. George's Hospital, and will give a series of lectures and demonstrations at the hospital next spring on the diagnosis of abdominal tumors.

**Dr. Thomas John Barnardo,** the well-known philanthropist of London who devoted his life to the work of rescuing street waifs in the English metropolis, died September 19 at the age of sixty years. He was a native of Ireland but received his medical education in Edinburgh, Paris, and London. While at the London Hospital in 1866 he had his attention directed to the children of the streets, and their rescue became his life work. He founded his first home in 1867. A village for girls followed in 1873, Her Majesty's Hospital for Sick Waifs was founded in 1887, and the Young Helper's League was formed in 1891. Through these institutions 55,000 orphan waifs have been rescued, trained and started in life; nearly 16,000 have been sent to Canada and the British colonies. Dr. Barnado was also a prolific writer on behalf of the cause of dependent children.

**Obituary Notes.**—Dr. Isaac Emmet Nicholson of Oakland, Cal., died September 9 from typhoid fever, at the age of thirty-four years. He was born in Oakland. He was a graduate of the Bellevue Hospital Medical School in 1894, and served as interne at Roosevelt Hospital.

Dr. Charles Smith of Guthrie, Oklahoma, died September 9 at the age of forty-eight years. He was born in Versailles, Ky., and was graduated from the Missouri Medical College, St. Louis, in 1879.

Dr. J. L. Wever of Leavenworth, Kan., died September 11, at the age of eighty-one years. He was born in Johnstown, N. Y., and was a graduate of the Albany Medical College in the class of 1852. He was surgeon to a Kansas regiment for three years during the Civil War. He was a member of the Leavenworth School Board for twenty years, and for six years was a regent of the State University; he was also chief surgeon to the National Soldiers' Home at Leavenworth.

Dr. Josiah Hale of Owensboro, Ky., died September 14. He was a graduate of the Medical Department of the University of Louisville in the class of 1856. He retired from active practice about ten years ago.

Dr. Hugh L. Tobin, physician to the Frankfort, Ky., penitentiary, died in Louisville, on September 14, at the age of forty-four years. He was a graduate of the Jefferson Medical College, in the class of 1882.

Dr. John B. Hardeman of Henderson Tenn., died September 10, at the age of sixty-two years. He was a graduate of the Medical Department of the University of Nashville, in the class of 1872.

Dr. Joseph M. Turney of Statesville, Tenn., died September 11 at the age of sixty-three years. He was a graduate of the Medical Department of the University of Nashville in the class of 1873.

Dr. Joseph Maurice Sheahan of Quincy, Mass., died on September 22, at the age of fifty-three years. He was born in Braintree, and received his medical degree from the University of Paris in 1879. He had practised in Quincy since 1880. He was at one time chairman of the Board of Health, and served on the School Board from 1886 to 1896.

Dr. Simon Fitch of Halifax, N. S., died on September 12, at the age of eighty-seven years. He was born in Horton and received his medical degree at the University of Edinburgh in 1841. He was the father of Dr. T. S. P. Fitch of Orange, N. J.

Dr. F. A. Baldwin of New York died September 22, at the age of fifty-nine years. He was a graduate of the Bellevue Hospital Medical School in the class of 1881.

Dr. Samuel C. Allaband died of apoplexy at Philadelphia on September 19 at the age of sixty-two years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1865.

Dr. Robert Ormiston of Brooklyn died at Stamford, N. Y., on September 19, at the age of seventy years. He was a graduate of the Medical Department of the University of Pennsylvania in the class of 1858. He served in the Civil War as an army surgeon. He was senior consulting physician of the Brooklyn Hospital for thirty years. He was a member of the Kings County Medical Society and the Brooklyn Pathological Society.

Dr. James R. Chadwick of Boston died suddenly at his summer residence at Chococura, near West Ossipee, N. H., on September 24. He was a graduate of Harvard Medical School in the class of 1871, and was a member of the Medical Faculty of the University.

## Correspondence.

### THE TREATMENT OF PNEUMONIA.

To the Editor of the Medical Record:

Sir: Your editorial in the issue of September 16 emphasizes the true state of this subject and suggests in its concluding sentence an important clue to the solution of the problem, "Why is pneumonia so fatal?" You say truly, "Perhaps an unprejudiced study of the methods of the many humble medical practitioners who do not write, and who have comparatively little bacteriological wisdom, but whose patients do not usually die from pneumonia, would help the commission toward at least a partial attainment of their object." It has always been a serious error to assume that the hospital physician, who sees a larger number of patients than the ordinary family physician, is best equipped for the determination of therapeutic questions. Statistics involving large numbers are constantly marshalled pro and con, when the treatment of any disease is under discussion, as trustworthy. There is no greater error. These statistics are drawn by reliable men—men who are, as a rule, competent; but the material from which the deductions are made is not the same as that which the family physician treats, nor do the conditions which influence the prognosis more than does the treatment by medicinal agents, which are still too much in vogue, approximate those in private practice.

In no disease is this more true than in pneumonia, as my personal observation as a hospital, institution, and private practitioner for twenty-five years has demonstrated.

1. Patients are sent to hospital usually after the disease has existed for days; often only when a fatal issue is evident or in prospect; almost always when the facilities of the house are inadequate for the proper care of the sick. Frequently the case has been treated symptomatically by antipyretics, or other powerful agents, before a diagnosis is made. This is not, as a rule, due to lack of skill. On the contrary, I have been greatly and agreeably surprised by the improvement in the management of the cases received at the hospital in recent years; chiefly in the cases treated by the younger men in the profession, who rarely depreciate the patient by powerful medicinal agents or stimulants administered too early, which always handicaps the subsequent treatment.

2. The constitutional stamina of the average hospital patient is inferior, despite the fact that he often looks more robust and muscular. Living in unsanitary environment, often deprived of means for ordinary personal cleanliness, nourished by cheap, therefore imperfect, food (as but too often demonstrated by rejection of large quantities of milk, the only food which is really under the most effective supervision by the health authorities), the men laboring hard during the day, but often spending part of the night in the saloons which abound in their vicinity; the women worn out with family cares or domestic service, these people are not endowed with the resisting capacity which is a potent factor in the prognosis of pneumonia.

3. The proportion of alcoholics is larger among the hospital patients than in ordinary family practice. If there be any one element which influences the issue of a case of pneumonia more than all others it is the alcoholic habit. Not the regular toper only, who goes on a spree or is found in the gutter is doomed; the man who must have a bracer before breakfast and numerous beers during the day; the woman who stimulates with tea, to cheer her care-worn brain, and joins her husband at meals in potations of beer; these are numerous among our hospital patients. It is singular that the average tenement-house dweller and his neighbor, the saloonkeeper, regard the taking of beer instead of gin or whiskey as a step in the direction of temperance. Last winter I had the privilege of seeing a case of pneumonia in consultation with Dr. Dew. Despite a good pulse, and the fact that the patient was robust and lived in a good house, he seemed to lose ground rapidly. When first seen, inquiry as to his habits elicited the information that he had abandoned "drinking" some months. The sudden development of feeble resistance to the toxemia, despite an involvement of only a small portion of the right lung, led us to inquire for details regarding his habits. It was now discovered that he drank only beer; and when his brother was pressed as to the quantity, he stated that he consumed about two gallons a day! In my last hospital service two patients with pneumonia were lying side by side; one, a Swede about fifty years old, thin, pale, and apparently of feeble stamina, but free from alcoholic habit, the other, a large, ruddy Irish teamster, middle-aged and swarthy, with cyanotic face and bounding pulse, who stated that he drank a good deal, but mostly beer. Both had been ill in bed several days. The temperature was high in the Swede and dyspnea pronounced, the pulse compressible but not very rapid, while in the Irishman the temperature was lower, the pulse full and bounding but more rapid. Reso-

lution began in the former on the second day after admission; the latter did not recover. The alcoholic cases are also fatal in private practice; the proportion is smaller.

The following clinical facts are offered to demonstrate the correctness of the views expressed above. In a paper read before the New York Academy of Medicine, on December 3, 1896, published in the *Medical News* (January 2, 1897), the mortality in 156 hospital cases of pneumonia before the institution of the treatment advocated in that article was *thirty-seven per cent.;* afterwards it was but twelve per cent. Without the exact figures it may be safely stated that the same mortality prevails in recent years. During a service of thirteen years in the New York Juvenile Asylum, a reformatory institution for over one thousand children, the mortality did not exceed three per cent.

In my private practice the exact number of cases treated during the past twenty years is not available; but the lowest estimate would probably reach 100 cases. The mortuary statistics of the New York Board of Health will show that I have reported but two deaths from pneumonia during the past twenty years. One of these was an alcoholic, the other a woman to whom I was called on the third day of her illness, when she had a temperature of 105 degrees F., and had had the incredible number of forty movements from a large self-administered dose of Epsom salts; despite this she had resisted confinement in bed. She survived three days. That my cases were not all of a mild type is attested by the fact that among those still fresh in my memory are several in old ladies; one, seen with Dr. E. H. Rodgers, was a diabetic with distinct acetonuria suffering from influenza, in the course of which both lungs were successively invaded. Three other desperate cases happen to be remembered because they occurred in colleagues. One was seen with Dr. Palmer Cole, who has reported the case; another with Dr. Ewing, and a third with Dr. Herff in San Antonio, Texas, where I happened to be sojourning for a few days.

It is unfortunate that few physicians preserve the records of acute cases, in order to afford evidence of therapeutic results and other valuable data. In cities, however, a resort to the Board of Health statistics would enable us to reach an approximate estimate of the fatality in our cases of pneumonia.

Let me not be misunderstood to assume that the method of managing this disease which has been on several occasions discussed in societies and in medical literature is advised as the only safe one. We must not forget what the wisest physician of all time has said: "Art is long, life is short, judgment difficult." But when the statistics of a hospital receiving mostly the worst types show an improvement of sixty-six per cent. in mortality, and private practice shows a reduction to almost no mortality, I may be pardoned for suggesting a fair trial of this simple method, which is but an evolution from an earnest trial of all methods passing through cupping, blisters, poultices, mercurialization, tartar emetic, veratrum viride, quinine, opium, antipyretics, *et id omne genus.*

Simon Baruch, M.D.

Hotel Majestic, New York.

## CANCER CURES.

To the Editor of the Medical Record:

Sir: In your number for September 9, on page 423, you state that "the question of the curability of cancer is likely to be brought . . . by a woman physician in Los Angeles against the State Board of Medical Examiners." Chivalry leads me to come to the aid of this oppressed lady; and therefore I beg to offer her, in support of her position, the testimony of several of your principal hospitals. By reference to their annual reports for the last twenty years you will see that they *cure* cases of cancer by the hundreds in the New York hospitals. Their exact methods are not given, but one is led to infer that they are surgical. Of this question of *cure* there can be no doubt, for these reports have gone on asserting it without contradiction for many years.

Respectfully,

Consistency.

Timbuctoo, September 12, 1905.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

CHOLERA—LONDON STATISTICS—MUNICIPAL FINANCE AND RATES—LIVERPOOL TROPICAL SCHOOL—MUNIFICENT GIFTS—HOSPITALS—OBITUARY.

London, September 8, 1905.

The march of cholera westwards has not been unobserved by our authorities, and the Local Government Board has now issued a circular to certain port and riparian sanitary officials. Cholera, it is pointed out, was present in Eastern Europe in 1904, and has now spread through Russia, reaching the Baltic, by way of the Vistula, in the persons of raftsmen descending that river. The cases that have occurred in East and West Prussia are therefore regarded as imported, no definite outbreak having so far been reported from any quarter of Western Europe. But the ports of the Baltic and some of the North Sea are threatened, and authorities of our ports trading with them should be on their guard against the importation of cases from such ports. In the event of a definite outbreak in any port of the Baltic or North Sea, it will be the duty of sanitary authorities to put in force the Board's cholera order (November, 1896) with regard to vessels arriving from such infected port.

With regard to the port of London, the medical officer, Dr. Herbert Williams, is making his preparations, or perhaps I should rather say, is fully prepared. He has four assistants, three of whom are stationed at Gravesend and one at Shearness. There are also three food inspectors and three steam launches are employed for boarding purposes. The regulations in force are considered sufficiently precise to cope with the difficulties of excluding the disease, or at least to reduce the chance of introducing it to a minimum. The medical officers all round our coasts are on the alert, and by no means disturbed at the prospect of a case being brought into the country unobserved.

In Prussia, the total number of cases reported officially up to the 4th inst. had reached sixty-six, of which twenty-three were fatal. The officials at the ports have taken all precautions.

A bulky volume entitled "London Statistics" has just been issued by the County Council. The "administrative" County of London (differing from "parliamentary" and "Greater" London) has an acreage of 74,830, and in 1901 the houses were 571,768 in number, the population 4,535,541, and the rateable £30,769,069. The vital statistics are given for 1902, the latest available returns of the Registrar-General. The births registered in that year were 130,478, the deaths 77,829, of which 13,352 occurred in workhouses, 10,722 in hospitals, and 401 in lunatic asylums. Street accidents caused 306 deaths and 39 were certified by coroners as due to starvation or accelerated by privation. From the observations of the guardians on these cases it would appear that most of them were due to disease caused by want or exposure, and in many instances to self-neglect. The average number of paupers on the books of unions every Saturday in 1904 was 114,470, being 72,885 indoor and 41,585 outdoor. On January 1, 1904, there were 19,087 indoor children. The cost of Metropolitan pauperism (year 1902-3), was £3,593,984. For every £1 spent on out-relief £7.12.4 was expended on in-maintenance. Detailed information on many other points and on the other "Londons" is contained in this heavy volume.

Increase of rates and the extravagance of local authorities continue to excite discontent and even threats as to what ratepayers will do. But they do not combine to dismiss those who squander their money and replace them with honest men of business capacity. It seems a monstrous thing that millions should be entrusted to men who have never had to deal with hundreds. Yet there are many who have got elected on local boards who have no financial knowledge whatever, and aspiring politicians do not weary in flattering the wage earner who has a vote that he is a fine representative of the race and fit to manage the education of the country or command the army or the fleet. So the murmurs go round about this and that expenditure, while the grumblers do not trouble to go to the poll and vote for better candidates. Exposures of ineptitude have no effect, and some of them seem incredible. Here is one for which a clergyman vouches. A boy sent to school fasting was asked why he had had no breakfast, and declared his father had no food in the house. The teacher, noticing his bulging pocket, asked what he had there, and was promptly answered, "Oh, that is my dinner."

This at the time Sir J. Gorst was advocating the free distribution of food to school children was at least calculated to give rise to doubts about the "independence of the British workman." An equally significant case lately came to my knowledge in which four boys in one family obtained a new pair of boots each at the expense of the rates by going to school successively at short intervals in an utterly worn out pair and declaring, on the teacher's questioning, that they had no others. The father boasted of his shrewdness, but one of his mates told him to his face he was mean.

Among other curiosities, that of local boards giving soap to tramps in the hope it will not be exchanged for beer, is amusing enough, but what of providing indoor pauper children with sixpenny cakes of scented soap? This on the recommendation of a woman doctor, whose fitness for her position seems to me doubtful.

Yesterday there was made public the full report of the Government Board's auditor on the East Ham District's

accounts, in which very serious complaints are made—disallowances and surcharges on the members of the late council are levied. Such irregularities as borrowing at 4 per cent. and relending to practically the same persons at 2½ per cent. are mentioned, and also a voucher prepared for the purpose of misleading the auditor. No doubt investigation will follow, and, indeed, the Borough Council at once appointed a committee. But the facts stated are enough to show financial incapacity, if no worse, and other boards are, I believe, in a similar case. Yet these frequent exposures only produce indignant protests by the ratepayers, who go on reelecting people of the same class. Perhaps some day they may rise in their might and put municipalities in commission, after the pattern of your Washington, D. C.

Professor Boyce, of the Liverpool Tropical School, now in New Orleans to investigate yellow fever, has been requested to proceed to British Honduras before returning, to report on the late outbreak there. From Brazil we hear that both members of the expedition from the Liverpool school have suffered from yellow fever, one very seriously.

Mr. E. G. Bawden, a member of the stock exchange, has entrusted to his friend, Mr. E. Speyer, cash and securities to the amount of £100,000 "to be applied to purposes of charity and benevolence, and for the advancement of knowledge, especially in aid of human suffering." Mr. Speyer has announced the institutions which he has selected to share in his friend's munificence, and naturally hospitals come in for considerable gifts.

The honorary secretaries of the King's Hospital fund have received £10,000 to be retained as capital, being part of a bequest made by Miss M. F. Hasker, of St. Leonards, to be devoted to charity at the absolute discretion of her executors.

At a court of Governors of the London Hospital on Wednesday, it was reported that an opsonic department for the treatment of patients by antitoxins had been formed under the control of Dr. W. Bulloch, and that excellent results had already been obtained.

The death of Dr. Thos. H. Littlejohn, M.O.H. for Hampstead, took place on the 4th inst., under sad circumstances. He was a very active and zealous sanitarian, and of late had suffered a good deal from insomnia. To this was added severe toothache, and he retired early to bed and took a dose of sulphonal. The next morning, as he did not wake, medical aid was called in, but he did not revive sufficiently to enter into conversation, and gradually sank. The medical evidence went to show that the fatal issue was due to the effect of the sulphonal on a weak heart. He was only thirty-eight years old. He was a son of Professor Sir Henry Littlejohn, of Edinburgh, where he was educated, graduating M.B., and C.M. in 1889, taking D.P.H. in 1892 and F.R.C.S.Ed. the following year. He received the Hampstead appointment in 1901, having previously occupied the officership of Scarborough. His energy was greatly appreciated by the Hampstead authorities, and many friends lament his untimely decease. Much sympathy is felt for his wife and his father.

The death is also announced of Dr. Cyril Henry Cayley, medical officer of the Bombay Municipality which occurred on July 31, in his fortieth year, from tetanus. This followed an injury to one of his fingers. On the appearance of trismus an operation was performed, but did not arrest the disease. His colleagues made every effort to save his life, but without avail. He went to India some years ago to take part in plague duty, and eventually was elected to the Bombay officership. He was a Cambridge graduate A.M., M.D., 1899, his bachelorship dating 1891. Two years before the last date he took the London double qualification and served resident offices at the Middlesex hospital.

Dr. Farquhar Matheson, J.P., surgeon to the Royal Ear Hospital, died an August 23, aged sixty-six. He was M.B., C.M., Aberdeen, 1868. He held several honorary appointments and contributed to the journals on points connected with his specialty.

Dr. Wm. Fuller, J.P., of Oswestry, died on the 29th ult., within a week of completing his ninetieth year. He graduated M.B., Dublin, 1842, having previously taken the surgical and some other minor diplomas in Dublin. He then settled in Oswestry, where he practised for some forty years, afterwards retiring from active work and attending to his duties as a magistrate as long as he was able.

Thomas S. Howell, of Wandsworth, died on Tuesday at the ripe age of eighty-two. He took his college and hall diplomas in 1844-5, having studied at St. Thomas's Hospital.

---

**Large Vesical Calculus.**—C. Duer describes in the *British Medical Journal* of July 15 the case of a man thirty-seven years old, who had for fifteen years suffered with stone in the bladder. Litholapaxy was impossible on account of the size of the stone, and so suprapubic cystotomy was performed, and the stone crushed by a lithotrite. When dry, the fragments of stone weighed 13 oz. 6 dr.

## OUR LETTER FROM THE PHILIPPINES.

**(From Our Special Correspondent.)**

TYPHOID IN MANILA—THE PLAGUE—THE MENACE OF CHOLERA—SMUGGLING VEGETABLES THROUGH QUARANTINE—PERSONAL ITEMS.

MANILA, P. I., August 15, 1905.

THE question of the prevalence of typhoid fever in Manila is now being investigated by the Board of Health. Considerable doubt has arisen as to whether the comparatively large number of deaths reported from typhoid fever are perhaps not due to other causes. For instance: Last month thirty-five deaths from typhoid fever were reported from the Ermita district, and that section of the city is always spoken of as being the most healthful of any. All physicians of the city have been requested to notify the Board of Health whenever a case of enteric fever occurs in their practice. With the attending physician's permission, a medical inspector of the Board of Health visits the case, makes a note of the symptoms, takes a specimen of blood, and sends it to the laboratory for the purpose of having a Widal test made. This method has been in force now for two weeks, and a considerable number of cases have been investigated; but so far no cases of enteric fever have been found. One curious condition has been revealed by the investigation of this disease in the provinces. It has been found that the disease is not infrequent among the Igorrotes. It will be remembered that this tribe belongs to the least civilized of all the various tribes in the islands, and are popularly known as "head hunters." They live in the mountains, and eschew all food ordinarily used by civilized man. Their meat diet consists principally of dogs, and it is possible that the dogs may have eaten the feces of some of the white gold miners who often prospect over the country occupied by the Igorrotes. The miners have been known to have typhoid fever, and they may have conveyed it, by such indirect means, to the natives. The Japanese who have been working on the Benguet Road have had outbreaks of typhoid fever occur among them several times. In their cases it is possible that the germ was introduced in the uncooked food which they import from Japan. Perforation occurred in two of the cases treated by Dr. J. B. Thomas, physician in charge of the Benguet Sanatorium. He operated upon the patients, one of them recovering, and one died.

The Philippines have been exceptionally free from plague during the past month. No case was reported between July 6 and August 7, 1905. While the disease seems to have subsided this year much earlier than usual at Hong Kong, Amoy, and Fu Chau, yet they still have a great number of cases, and the insular quarantine authorities continue to enforce rigid quarantine measures against these ports.

The Philippines are menaced by the appearance of cholera at the ports of Hong Kong and Shanghai. Vessels arrive almost daily from Hong Kong, and the cargo which they bring—or, rather, attempt to bring—often consists of low-green-growing garden truck, which has been fertilized and sprinkled with liquid human excrement. The ease with which it may be impregnated with cholera organisms is apparent. Such vegetables are not grown in the Philippines, and when it becomes necessary to prohibit the entrance of the same it can readily be understood that the prices immediately rise, which makes their successful introduction very profitable. For that reason the shippers often falsely manifest a cargo, with the hope that it may escape detection at the port of entry into the islands. It is said to be a not uncommon experience for the quarantine authorities to find cabbage and celery in the middle of a box containing socks and other drygoods. In view of the foregoing, it will be seen why the appearance of cholera at nearby ports is viewed with great apprehension by the officials who are responsible for the health of the islands. Hong Kong is only two days' sailing distance from Manila. It is essential for the welfare of the islands that the shipping between these ports be interfered with as little as possible, and since the incubation period of cholera is five days, it is quite possible for an individual to be in the incubation period of the disease upon his arrival here, and, in consequence, escape detection by the quarantine officials, unless vessels are held in quarantine to complete five days.

Major Guy Edie of the Army Medical Service arrived in the Philippines from Washington during the week with the Secretary of War and his party, who are making a tour of inspection of the Philippines. He is acting as the attending physician to the Secretary, and will return with him to Washington. Surgeon Edie was the first American president of the Manila Board of Health, and has the honor of having started much of the health work which has resulted in so much improvement in the sanitary condition of Manila.

Dr. J. B. Thomas has resigned his position as Physician in Charge of the Benguet Sanatorium, and has returned to

the United States, where he will engage in private practice in California.

Major Edward R. Morris, surgeon, United States Army, has been granted thirty days' leave of absence, with permission to visit Japan, and, at the expiration of his leave, he is relieved from further duty in the Philippines Division and will proceed to San Francisco and await further orders. Major Morris has been on duty at Iloilo during the past two years as surgeon in charge of the army hospital at that place.

## Progress of Medical Science.

*Boston Medical and Surgical Journal. September 21, 1905.*

**The Medical Treatment of Gastric Ulcer and Hyperchlorhydria.**—For hyperchlorhydria F. C. Shattuck advises the free use of sodium bicarbonate in plenty of water. If used in the familiar tablet, the mint element of the latter should be left out. If constipation coexists the milk of magnesia is useful, but it may act on the bowels too freely if the degree of hyperacidity is great. The diet should largely exclude salt, the source of HCl. Meat and fish are to be temporarily cut off; milk and eggs, soft boiled, dropped, or scrambled, are allowed. In severe cases from one half to two drachms of bismuth subnitrate may be given before meals. It probably acts as a protective coating to the gastric mucosa against the food, and this diminishes the peptic activity. Cases presenting severe and characteristic ulcer pain call for rest for some days from gastric digestion. Morphine in small doses by the mouth may blunt an appetite, not then safe to indulge. Peristalsis is quieted and glandular secretion diminished. After three or four days of exclusive rectal feeding, milk and lime-water, a drachm every fifteen minutes, can be given by the stomach with daily increase in the amount, lengthening of the interval, or both. In ten to fourteen days milk toast, junket, rice with cream and sugar, baked potato, macaroni, blancmange, and the like may be added and rectal feeding omitted. Shattuck believes that in these cases abstinence from meat should be prolonged for at least three months. Food containing starchy things, such as unstrained oatmeal, seed fruits and the like, is also to be excluded lest it irritate the raw surface. The principle is simply to select such food as demands the least stomach digestion and to avoid irritation as far as may be. Bismuth is desirable until full and ordinary diet has been resumed, say three to six months. It here serves a double purpose, diminishing secretion and also mechanically protecting the raw surface from both food and such gastric juice as is formed.

*New York Medical Journal, September 23, 1905.*

**The Menopause.**—J. N. Upshur describes the various nervous disturbances incident to the menopause and emphasizes the fact that at this period the woman has a special susceptibility and lessened resistance toward disease. There are three general types of patients: plethoric, chlorotic, and nervous. In the treatment of these conditions, the chief aim is to sustain the system in such a way as to allay nervous irritation and supply stimulus and nourishment which shall maintain as nearly as possible the normal standard of health. Drugs are to be avoided when simpler and less active agents will suffice. Especially pernicious is the injudicious prescription of narcotics and alcoholic stimulants. Change of scene, regular exercise, etc., are to be secured. Insomnia may be avoided by the administration of some form of concentrated nourishment such as hot milk; just before the patient retires, a warm salt bath is most soothing to the nervous system. Regular daily use of massage and electricity, faradic or galvanic, may be indicated. Very plethoric patients may be helped by venesection. Drugs must be our last resort though ovarian irritability must be controlled. Marriage during this period is to be deprecated, although the stress of sexual appetite may be felt as never before. The views of Tilt are quoted to the effect that "increased sexual appetite at this period is a morbid impulse, dependent upon some neuralgic or inflammatory condition of the uterus or ovaries. Marriage at this period, or too frequent sexual intercourse in the married, may result in obstinate uterine disease, menorrhagia, cancer, etc., or some women may become insane."

**The List Practice.**—By this term D. W. Bedinger refers to the custom of some corporations which pay a fixed sum to a physician for services to their employees, a certain deduction being made for this purpose from the latter's wages. The advantages to the physician are, certainty of payment, opportunity for scientific observation of the patient (the latter not caring how many visits the doctor makes) and the reduction to a minimum of the unpleasant rivalries of small town practice and the fact that the physician makes a living from the start. The disadvantages are that owing to the small sum paid by each employee, the physician loses caste to some extent with his patient. Moreover, under this system the physician is often needlessly called. The charge per visit amounts to about forty cents. Bedinger believes that three-fourths of the physician's troubles are traceable to the fact that the subscriber may summon him without the cost of an extra cent. Consequent upon this follows the large number of unnecessary calls; the loss of respect for medical attention; the enormous loss of time, and the limited earning capacity of the physician. Therefore to eliminate the feature of unlimited calling would, to a large extent, result in the elimination of the disagreeable group of consequences that follows in its train. The author suggests as a remedy a slight reduction in the amount of the monthly assessment and the establishment of a slight charge for each visit.

*Medical News, September 23, 1905.*

**Appendicitis in Children.**—A series of seventy cases occurring in children is reported by C. N. Dowd, who divides them into three classes: 1st, early, or operations within the first two days; 2d, later, active cases whose operations came during the progressive or retrogressive stage of the disease, and 3d, interval cases whose operations came after the inflammation had subsided. These groups are then studied and analyzed, and as a result of this study the author offers the following observations: (1) The rapidity and insidiousness of the disease are much greater in children; (2) the percentage of diffuse and general peritonitis is greater, probably because the omentum is less apt to inclose the inflamed appendix; (3) the pain is almost always present, but is more difficult to interpret; (4) the vomiting is almost always present and is frequently many times repeated; (5) the abdominal palpation in the majority of cases is as satisfactory or more satisfactory than in adults, but in a few cases is absolutely misleading; (6) constipation is much less likely to be present. (7) they have a greater ability to deal with general peritonitis than adults do; (8) during the acute progress of the disease delay is more dangerous than in adults, because of the insidious course of the disease and the greater tendency to peritonitis, and immediate operation is to be advised.

**Ovarian Transplantation.**—J. P. Warhasse reports a case illustrative of cachexia ovaripriva following the removal of both ovaries, the relief of symptoms by the use of ovarian extract, the cure of the condition by the transplantation of ovary from another woman, and the final recurrence of the disturbances at the end of the year. His patient was a woman of twenty-seven years, from whom one ovary and both tubes had been removed for double pyosalpinx and a hysterectomy was also done as the uterus was involved in the inflammatory products. She presented the usual symptoms of fainting attacks, hot flashes, gastric crises, nausea, vomiting, perversion of sensation, dizziness, constipation, etc. Ovarian extract in five-grain tablets taken three times daily for about two weeks out of each month kept her fairly comfortable, but its continuance was followed by a return of symptoms. Finally an ovary which had been removed from another patient on account of a small cystoma (which was cut away from the organ leaving a mass of apparently healthy tissue), was implanted in a slit made in the right broad ligament of Dr. Warbasse's patient. Less than one minute was consumed in the transit of the ovary from one patient to the other. The next menstruation occurred in about ten days and was passed through with but little trouble. Following this the nervous symptoms and signs of the cachexia failed to appear for nearly a year, and the patient was able to return to business. At the end of that time the old symptoms began to reappear and while they have not been as severe as formerly, the good effects of the operation have seemed to be gradually passing away.

**What Means Does the Modern Obstetrician Employ to Prevent Ophthalmia of the Newly Born?**—In institution practice J. C. Edgar advises vaginal cleansing with mild alkaline douches followed by sublimate 1-5000 for two weeks before delivery. Immediately before confinement lysol may be used for lubrication. In private practice he usually omits this antepartum vaginal cleansing. After delivery he follows the Credé method of installation and after a trial of various salts he finds nothing to compare as a prophylactic with a silver nitrate solution of two per cent. strength. As soon as the child is born its face is carefully washed with boric acid solution, separate wipes being used for each eye, and the lids rubbed from the nose outward in each case. Then whether infection is suspected or not, two drops of a two per cent. solution of silver nitrate are dropped into each conjunctival sac. The excess is washed away in about thirty seconds with a saline solution. In Edgar's experience, solutions of

less than two per cent. do not destroy bacteria, and althuogh solutions of three per cent. are harmless, they are apt to cause "silver catarrh," and are not required.

*American Medicine, September 23, 1905.*

**Digitalis in Valvular Heart Disease.**—Max Goepp says digitalis increases the contractions of the heart and lengthens the intervals of rest (diastole); at the same time the nutrition of the muscle is increased because more blood is forced into the coronary arteries. The indication for digitalis is found in the dynamic state of the circulation, the precise nature of the cardiac lesion being of minor importance. It may be indicated in any form of valvular disease and is not counterindicated even in aortic insufficiency. Counterindications for the use of digitalis are: hypertrophy with established compensation, degeneration of the myocardium, and high arterial tension. The cumulative action of digitalis may be disregarded and the administration kept up continuously for a considerable period. The best preparation is the infusion made from the powdered leaves of digitalis, and not, as is sometimes the case, by diluting the fluid extract. Digitalin is a useful preparation and can be given hypodermically. It should, however, be given in considerably larger doses than is usually recommended. It is well to begin with 3 mgm. (1-20 grain), but no hesitation need be felt in increasing the dose up to 5 mgm. or 8 mgm. (1-12 or 1-8 gr.)

**Therapeutics of Acute Insanity.**—Daniel R. Brower says insanity is a profound error in general metabolism, which may sometimes be overcome by alteratives; mercury, potassium iodide, and the chloride of gold and sodium. In considering the therapeutics of acute insanity, we must ever be mindful of the necessity of attention to the general constitutional state of the patient. Rheumatism, gout, tuberculosis, and syphilis require special consideration. Special attention must also be given to elimination by the bowels and kidneys. Intestinal fermentation, when present, must be diminished by intestinal antiseptics, of which salol and zinc sulphocarbolate are among the best. Disorder of the gastrointestinal tract is one of the most common errors in these cases. Colonic impaction is common, and is frequently overlooked, and its relief by aloetics and flushing resorted to early, will often change the whole aspect of the case.

**Three Cases of Cancer of the Body of the Uterus.**—Frank C. Hammond reports three cases of cancer of the body of the uterus illustrative of interesting points in the diagnosis of this disease. If success is to be obtained in the treatment of cancer of the uterus, the practitioner must realize the inestimable importance and value of early diagnosis and early radical operative procedures. When the cervix is normal and the patient presenting suggestive symptoms of malignancy do not lose sight of the fact that malignancy of the body of the uterus may be present; this occurred in one of the cases. Attention is called to the one fact which is impressively evident, that is, the steady increase of cancer of the uterus in young women. Every woman who is bleeding should be subjected to an immediate pelvic examination, and the reappearance of hemorrhage, one, two or three years after the menopause is strongly presumptive evidence of cancer of the uterus. Stress is laid upon the necessity of the practitioner making an early diagnosis, and not waiting for the four cardinal symptoms—pain, hemorrhage, fetid discharge and cachexia, for by the time these are all present, the case as a rule is inoperable. The earliest symptom in the majority of cases is bleeding, and should at once place the physician on his guard, irrespective of the age of the patient. A slight watery discharge occurs in some cases early, instead of the bleeding, and is highly diagnostic, especially when malodorous.

**Pathology of General Paralysis of the Insane.**—John D O'Brien concludes that the importance of an antecedent syphilitic infection in general paralysis, and the action of such in the production of the disease, leave much doubt, but it is safe to say that it is undoubtedly a predisposing factor, and probably acts by weakening the immunity. Almost all authorities at the present are satisfied that general paralysis is a toxemia, a bacterial toxemia, as evidenced by the temperature, leucocytosis, the progressive course, and now the finding of an organism, to which we can attach considerable importance. This organism, diphtheroid in character, has been studied by Ford Robertson, McRae, and Jeffries, who first called our attention to it. Its cultural and morphological properties to a certain extent resemble those of the Klebs-Loeffler bacillus, and they think it may be merely an attenuated or saprophytic form of the true Klebs-Loeffler bacillus, which, by its long residence, may have undergone a certain exaltation of virulence. In a search for this organism the stomach wash of 14 general paralytics, who had been fasting, was obtained, and in 11 cases this organism predominated. In the examination of the urine of 10 cases, the organism was isolated in 7 instances. The examination of the throat and nose of 12 general paralytics recalled the presence of this diphtheroid organism in 10 instances; the only cases of general paralysis in which they failed to obtain this organism were those in a state of remission. The author believes that the organism is present even before any symptoms appear. Further experimental investigations, such as inoculation of rats and guinea pigs, led to the production of some few subjective symptoms of general paralysis of insane. These are some facts which tend to support the view that this diphtheroid organism is undoubtedly exerting a pathogenic action, and it remains for future investigation to establish it more thoroughly.

*Journal of the American Medical Association, September 23, 1905.*

**Abdominal Crises Caused by Meckel's Diverticulum.**—M. F. Porter calls attention to the accidents that may be caused by the presence of a Meckel's diverticulum, an anomaly that probably exists in one or two per cent. of all individuals. He has collected altogether 184 cases of abdominal accidents from this cause, of which he gives brief abstracts, including 35 not heretofore published. Intestinal obstruction by band occurred in 101 cases, volvulus in 8 cases, intussusception in 20, diverticulitis in 17, prolapse of the bowel through a patent diverticulum in 2; typhoid perforation in 5, traumatic perforation in 1 and tubercular ulceration in 2 cases. In the 21 cases of hernia reported in the paper the diverticulum was the cause of the trouble in all but one; in that one it was simply noted as forming the content of the sac. The average age of the patients was 21 years and 2 months, but the list includes six over 50, one patient being 81 years of age. In 5 cases the diverticulum was patent at the umbilicus. Symptoms of acute obstruction were manifest from the start in 118 cases and incomplete obstructions were present throughout in 7. In 17 cases there had been attacks of incomplete obstruction prior to the final acute attack. In 20 cases the symptoms were those of general or circumscribed peritonitis. Appendicitis was diagnosed in many cases, and was a complication in one. The proportion of males to females was 3 to 1, suggesting trauma as an important cause. The total mortality was 60 per cent., and of those operated on 50 per cent. Except in cases patulous at the umbilicus, there are no distinctive symptoms pointing to the diverticulum, and in only one of the cases was it diagnosed prior to operation. In conclusion, Porter urges the removal of all diverticula met with in abdominal operations, whether the cause of trouble or not, provided the exigencies of the case in hand do not contraindicate further operative procedure.

**Freezing Points of Blood and Urine in Pneumonia.**—F. E. Schmidt after first reviewing the literature of cryoscopy in medicine, and especially in pneumonia, describes his methods and precautions for thus testing blood and urine and gives tabulated details of observations in twenty-four cases of pneumonia in males between the ages of 18 and 50 and all apparently in good health before the attack. The tests were made daily the patients being given essentially the same diet of milk and later broths and plenty of water and kept under the regular stimulating treatment A few had salt irrigations. The freezing points of the blood and urine, the quantity and specific gravity of the urine and the amount of urea were recorded and albumin and casts noted when present. He finds that there is an absolute lowering of the freezing point of the blood in pneumonia depending in some way either on the extent of consolidation of the lung or on the height of the temperature or both. This lowering is more than can be accounted for by the increased venosity of the blood from deficient aeration. The concentration of the blood increases, as shown by the lowered freezing point, as the disease progresses up to the time of crisis. Some time is needed for the elimination of the excessive accumulation of products in the blood, hence several days elapse before the freezing point rises again to normal. In cases in which the heart perceptibly weakens, the freezing point becomes still lower, and in fatal cases when the heart gives out, the freezing point of the blood is extremely low. The lowered freezing point of the blood is apparently not due to deficient kidney function, but may be due to the inability of the kidney to excrete the excessive products of metabolism. The freezing point of urine in pneumonia is considerably lowered, more than would be accounted for by a mere concentration of normal urine The chlorides excreted are diminished, on account of a lesser amount taken in (Sollmann). The quantity of the urine is decreased while the freezing point is lower, and this lowering is not due to chlorides but to metabolic molecules excreted. The freezing point of the urine does not rise to normal until after that of the blood, that is, several days after the crisis. The specific gravity of the urine is no accurate index of its degree of concentration The freezing point of the urine

bears no constant relation to that of the blood normally, for with a freezing point of blood at—0.54 C. the freezing point of the urine may be normally lower than in a case in which the freezing point of the blood is —0.57 C., or *vice versa*.

**Pleural Effusions in Children.**—C. F. Wahrer remarks that pleural effusions in children are not by any means always tuberculous and that they often escape diagnosis. He points out the methods of correctly ascertaining their presence, including exploratory aspiration by which alone can be ascertained the character of the effusion In children under three, it may be stated as a general fact that the effusion is usually purulent. The importance of correct diagnosis is the greater since in most undiagnosed cases the patients die, while with proper treatment the prognosis is good, except under one year of age, when the disease is rare or when the disease is bilateral, which also is seldom the case. There is in children a more active metabolism and a greater elasticity of the chest wall, favoring the collapse of the smaller cavity. In the majority of cases, the treatment is surgical, and he believes that every physician competent to treat these cases should also be able to aspirate a serous effusion or to make an incision for an empyema in a child. Of course the more competent the surgeon the better, and in extremely rare cases where an Estlander or a Schede operation is required the highest possible surgical skill is none too good. The cases of two patients successfully operated on by incision are reported. The author concludes by urging most painstaking physical exploration in these cases, with all clothing removed and every possible available instrumental aid. Experience teaches him that too many auscultations are made with the unaided ear, too many percussions through clothes and poultices, and that there are too many snap guesswork diagnoses. The microscope and blood counts may aid.

**Immature Senile Cataract.**—A. E. Bulson, Jr., discusses the propriety of operation for the removal of immature senile cataract. He would operate in slowly progressing cases in which there are no contraindications aside from the semi-transparency of the lenses, and in which vision is so far impaired as to prevent reading of ordinary type, the patient having been fully informed as to the possibilities of secondary cataract requiring discission and mild postoperative inflammation with delayed recovery The essentials of a successful operation removing practically all of the cortex with a minimum amount of trauma and subsequent inflammatory reaction, and favoring such after-treatment as will limit the inflammation and promote resorption are: 1. A large corneal section, embracing not less than two-fifths of the corneal circumference; 2, an iridectomy with a fairly large coloboma extending to the ciliary border; 3, a large opening in the capsule by two incisions at right angles to each other; 4, gentle irrigation of the anterior chamber with a sterile normal salt solution, after the extraction of the nucleus, if much cortex remains; 5, the early and free use of atropin, and 6, the use of dionin, after the corneal wound has closed, to promote resorption of lens debris. The irrigation must be done with the utmost delicacy; the method he prefers is that of Lippincott, allowing a continuous stream to flow by gravity through a small specially constructed cannula introduced just within the lips of the corneal wound, the flow being completely under the control of the operator. To anticipate the slight iritis that is likely to occur, he begins the use of atropin at the time of the first dressing, from thirty-six to forty-eight hours after the operation. Bulson believes that the final results of removal of immature senile cataracts should compare favorably with the extraction of cataract in any stage. His personal experience with twenty-five cases has been very satisfactory. The article concludes with a long series of opinions of prominent ophthalmologists, obtained by correspondence, most of which express views largely in agreement with those of the author.

*The Lancet, September 16, 1905.*

**A Case of Wounding by an Unusual Projectile.**—The patient of J. S. Nicholson was wounded in a mining explosion and presented a compound fracture of the left femur, there being a ragged wound on the anterior aspect of the limb, in the depth of which a loose fragment of bone was seen. Examination of the wound showed this fragment to be loose and connected merely by a tag of fibrous tissue; this was severed and the piece was removed. It measured one and a quarter inches by a quarter of an inch by one-eighth of an inch and had one smooth surface. The curvature of this surface, however, did not correspond to that of the shaft of an adult femur. The wound was further explored and a mass detected in its upper part; this was removed and found to be a finger represented by the two terminal phalanges with about three inches of the flexor tendons attached. The first piece of bone was now recognized to be part of the proximal phalanx of this finger. The wound, which was fully five inches in depth, was douched out with solution of carbolic acid, lightly plugged with iodoform gauze, and healed without suppuration. The finger came from the hand of the man's companion, who was killed outright by the explosion.

**An Acute Illness Following Inoculation with Antityphoid Vaccine.**—W. J. Lindsay reports the case of a ship's surgeon, aged 29 years, who was inoculated once with the serum. There followed only slight local soreness and stiffness. Thre months later he was again inoculated under the usual antiseptic precautions in the subcutaneous tissue of the right side of the abdomen. Headache came on six hours later with the gradual development of a general malaise. On the third day evidences of local inflammation were noted at the inoculation site. A general septic condition now supervened, but after eleven days he was out of danger. The convalescence was uninterrupted except for a mild attack of urticaria at the end of the second week. Three possible diagnoses were considered by the physicians in attendance on the case, true typhoid infection, atypical typhoid, and toxemia following inoculation. Throughout, the illness resembled a moderately severe attack of typhoid fever, while the typical symptoms—bronchitis, rash, splenic enlargement, tumidity and tenderness of the abdomen, and diarrhea—were absent; the headache, insomnia, restlessness, marked prostration, the absence of physical signs of any demonstrable lesion, and the range and type of the temperature, all pointed to the possibility of typhoid fever. Moreover, the convalescence approximated to that following a mild attack of typhoid fever. Although there were no complications except the urticarial attack the feeling of weakness was prolonged and the normal health was not regained until six or eight weeks later. In general terms the author is sceptical of the prophylactic efficiency of antityphoid serum, and is by no means disposed to regard its employment as a trivial matter.

**A Case of Tuberculous Ulceration of the Colon Simulating Appendicitis.**—The case is reported by G. C. Turner, who was summoned to operate on a supposed case of appendicular abscess in a single woman of thirty-four years. Incision revealed, however, a normal organ, but a hard lump was found in the outer and posterior wall of the ascending colon. The subperitoneal tissues in the sulcus on the outer side of the colon were very edematous. The mass appeared limited to the bowel, for the latter could be easily rocked from side to side. There were no enlarged glands and no deposits on the surface of the peritoneum. The cecum appeared normal and there was no evidence of tubercle in the lower ileum. The sudden onset of the illness and the edema of the tissues around suggested an inflammatory origin, but the hardness of the lump made the operator very suspicious of new growth. If the mass was purely inflammatory it would be sufficient to leave in a drainage-tube and a gauze pack, treating the case as one would an infected area following appendicitis. If it was tuberculous, then a lateral anastomosis would relieve the patient meanwhile and give the ulcer time to heal; but if it turned out to be malignant, the most favorable opportunity for removing the disease would be lost. The lower two inches of the ileum, the cecum, and three inches of the ascending colon, together with the termination of the mesentery, were therefore excised. Examination of the mass removed showed tuberculous ulcer in the cavity surrounded by indurated tissues formed by the lump above mentioned. The author dwells upon the difficulty of a preoperative diagnosis of such masses occurring in the appendical region though, usually they are malignant. They may simulate appendicitis in one of three ways: 1. A growth in the cecum may be associated with attacks like appendicitis. These attacks may be due to obstruction or to inflammation of the parts around, and this may go on to the formation of an abscess which may exactly simulate one due to appendicitis. 2. A growth in any part of the large intestine beyond the cecum may get blocked, and if there is a competent ileocecal valve the cecum is the first part to feel the stress of the obstruction, and at first all the pain is referred to this region. It is only as the attack passes off that the falling distension enables the lump elsewhere to be felt. 3. Primary malignant disease of the appendix may be the cause of the symptoms.

**Some Remarks on the Germ Centers of Lymphatic Glands and Secondary Careinomatous Deposits.**—According to J. B. Cleland, a close resemblance often exists between these two forms of tissue, and doubtless they have often been mistaken the one for the other. The germ-center cells, however, are larger than the surrounding lymphocytes, and have more protoplasm and a larger and vesicular nucleus. The whole area stains, too, to a much lighter degree than the parts around. Mitotic figures are nearly always numerous, and at the edge of the area the cells rapidly, but by distinct gradations, become converted into lymphocytes, so that no hard and fast line of demarcation limits the area. The areas are usually small and indistinctly circumscribed

and in such conditions are not likely to be mistaken for a cancerous growth. In certain circumstances, however, associated with chronic irritation, they assume a most striking appearance. This is associated with increase of size and great increase of mitotic activity in the areas, and suggests the idea that it is a form of compensatory hypertrophy. These germ centers form sharply defined spherical or oval areas. The cells composing them are of a nearly uniform size and a little smaller and more regular than those of cancer. They are closely packed with very little stroma. An occasional capillary vessel may be noticed. The nucleus closely resembles that of an epithelial cell, and mitoses are quite as numerous as in cancer. The most important difference, however, is found in the boundary zone of each. The somewhat larger and more irregular cells of cancer are sharply and distinctly separated and often by a thin zone of fibrous stroma from the surrounding lymphocytes, and each individual cell at the periphery can be relegated at once to one or the other class of these two, but in the outer zone of the germ centers cells and lymphocytes tend to be arranged in concentric rings formed of a delicate fibrous tissue, and all gradations are seen between undoubted germ-center cells, on the one hand, and undoubted lymphocytes on the other. Under a low power of magnification the germ center often seems sharply delimited from the surrounding parts, and the cancerous deposit is less distinctly outlined; with higher magnifying powers this appearance is reversed and the germ center is found, on careful observation, to grade into the lymphatic tissue around while the carcinomatous growth is sharply defined.

*British Medical Journal, September* 16, 1905.

**An Investigation on the Regeneration of Nerves, with Regard to the Treatment of Certain Paralyses.**—Basil Kilvington declares that both clinical and theoretical considerations point to nerve splitting being preferable to suturing two distal nerves directly to the central end of one of them. In one of the dogs operated on it was later noted that the function of the leg from which a bit of the external popliteal had been excised was not so good as it had been a week or two previously. When the wound was reopened it was discovered that the bulbs had fused considerably. Where the bulbs fused, fibrils from one axis cylinder presumably grew down into the two distal nerve trunks. The separation of the bulbs, although it destroyed a good many fibers, resulted in a rapid and considerable improvement. The writer states that in facio accessory anastomosis it would be wise to split the latter nerve into two strands, injuring the actual nerve fibers as little as possible. One of these should be attached to the distal cut end of the facial, and the other to the whole of its own distal end. This would abolish associated movements of the shoulder, or at any rate, reduce it to a very small amount, for a few fibers at the angle of splitting would possibly be injured, resulting in their growing down the nerves to both sets of muscles. No very considerable atrophy of the muscles would take place after this, as the fibers of the central end would multiply at the point of suture. The writer suggests that nerve splitting should be made use of in the treatment of suitable cases of anterior poliomyelitis for the same reason.

**A Probable Explanation of Some Drowning Accidents.**—Hugh Lawrie describes an experience of his own from which he draws certain conclusions. He went in swimming in cold water on a hot day after he had been cycling. His stomach was empty of food at the time. His head began to ache, he became giddy and drowsy, and muscular effort became feeble and sluggish. In many instances the swimmer simply loses consciousness from cerebral anemia. In other words, he faints, and without immediate assistance he goes under and loses his life. This is far more probable than that he "was seized with cramps and sank." The writer believes that all those who are in the habit of swimming in deep water should from time to time have a medical examination. The medical inspection will reveal any cardiac affection, and at the same time a study of the digestive system will bring out any points pointing to atony of the stomach walls with consequent distention by gas. Any attempt at prolonged swimming is a positive danger in an atonic condition. The best time for a swim is probably about two hours after breakfast or lunch. Swimming in cold water is dangerous when the intestines have been emptied by a purgative and the circulation probably thus depleted. There is then low-tension circulation, especially if there has been a fast of several hours. Instruction in the physiology of bathing should be given to the members of every swimming club, and to all boys and girls who are learning the art.

**A Method of Guarding the Perineum in Labor.**—W. J. Cale points out various factors which he believes contribute to the injury of the perineum: The attempt to pull forward the vertex by passing the left hand between the thighs of the mother and employing traction on the scalp; "supporting the perineum" in the direct method by pressure thereon of the concavity between the thumb and forefinger of the right hand; the endeavor to push the fetal head forward by the indirect method either by inserting two fingers in the rectum or by pressure behind the anus; the common delivery of the shoulders. The writer believes that there is no necessity for passing the arm between the thighs of the mother. When the head is moderately distending the perineum, the latter and the adjacent parts are dried with a hot sterilized towel. When the tension on the perineum is approaching its maximum, the left hand of the accoucheur presses slightly upon the vertex to prevent sudden expulsion. The right hand should then grasp the perineum, but between it and the perineum a hot sterilized towel is placed so that the edge of the concavity between the thumb and index finger, the edge of the towel, and the lip of the perineum are just in line with each other, a double fold of towel fitting into the apex of the concavity to supply the deficiency. Firm pressure is exerted at every pain through the bitemporal diameter of the fetal head, if there is any tendency to laceration. No attempt is made to push the head forward till the occiput ceases to engage behind the pubic arch. After the head is born, gentle traction is exercised backward and the next pain will generally cause the anterior shoulder to free itself from behind the pubic arch, while the perineum lies over the posterior shoulder and is subjected to only a moderate degree of tension. If the outlet is narrow, the anterior arm can usually be extracted with very little difficulty after the anterior shoulder is born, thus substituting a much smaller diameter of the child. The writer has followed out these lines in about four hundred consecutive cases of labor, and has found the method singularly effectual.

**A Case of Quadruplets.**—Llewellyn W. Roberts reports this unusual case. The mother was 32 years old, of French extraction and married twelve years. She had had six previous confinements, resulting in the birth of ten children: Twins, triplets, a single child, twins, and two single children. All lived except the triplets, which were seven-months' infants. Eighteen months ago, she had placenta previa. When she was, this last time, eight months pregnant, slight uterine contractions came on and she was delivered of quadruplets. There were four distinct and separate placentas about five to six inches square, and four separate bags of membranes. The second and third placentas were found united by a band of membrane. The third child was stillborn, but the mother and the other three children have done well. Each child, two boys and a girl, weigh about five to six pounds.

*Berliner klinische Wochenschrift, September* 4, 1905.

**Should a Mother Having Scarlatina be Allowed to Nurse?**—Salge answers this question in the affirmative, and says that the current tendency both among the laity and medical men to accept all sorts of disturbances of the health of the mother as an excuse for stopping nursing is quite unnecessary. It is supposed that the milk will be injurious, or that the child will be infected, etc., but this is not the case even in dealing with the acute infectious diseases. The author describes the case of a girl of 17 who about six weeks after confinement developed scarlet fever, which ran a course of medium severity. Up to the fourth day she was able to satisfy the child's hunger, but from then until the seventh day bottle feeding was given in addition, and after that the milk ceased entirely. On the eleventh day it appeared again, so that the mixed feeding could be resumed, and after the twenty-sixth day the artificial food was dropped entirely. The child did not suffer at the time nor subsequently. Breast milk confers on the child an enhanced power of resistance against all infections, and its value is so great that tuberculosis is the only disease which, as a routine measure, demands weaning. Measles and diphtheria do not, though in the latter case the infant should be immunized.

**The Spirochæta Vaccinæ.**—Marbury describes a number of differently shaped organisms which he has discovered in smallpox or vaccina pustules. He considers these as being related forms of the causative agent of the disease. Some of them are in the form of spirochætæ, others are comma-like organisms, and, finally, there are larger, irregularly triangular forms with two long, very delicate, wavy prolongations at two of their angles. The spirochætæ, he believes, are composed of comma forms joined end to end, and he considers that this shape is assumed when life conditions become unfavorable. The triangular bodies he regards as the fundamental type of the smallpox or vaccina organism, and suggests their possible relation to the trypanosomes.

**Endoscopy of the Sigmoid Flexure.**—Strauss discusses this subject somewhat at length, and speaks highly of the value of the method. He describes a special pneumatic apparatus he has devised which has magnifying and pho-

tographic attachments. He considers that the method is greatly superior to the use of bougies, as with the most approved form of these he has never been able to penetrate more than 12 inches from the anus. Sigmoscopy is especially valuable in cases of bleeding from the bowel, or of tumor masses palpable from without, and under such conditions it often offers the only means of making a positive diagnosis. The statistics of recurrences after the extirpation of rectal carcinomata are improving, but are still so discouraging as to emphasize the advisability of making free use of sigmoscopy in the interests of early diagnosis. Severe bleeding from the lower bowel always indicates the necessity for great caution in carrying out the operation, and under these conditions the author prefers the lateral position to the usual knee chest posture. Acute inflammatory conditions usually contraindicate the examination. A study of the comparative tonus of the anal sphincter and of that of the sigmoid flexure shows that the former is much stronger, so that injections large enough to more than fill the rectum are sure to reach the sigmoid. For this reason the author has given up the practice of inserting the irrigation tube into the sigmoid by the aid of the sigmoidoscope, but when it is desired to medicate the upper bowel simply uses an injection of one and one-half liters, experience having shown that this amount completely distends both rectum and sigmoid. For cases in which the sphincter ani is weak he has invented an irrigation tube with an inflatable rubber collar, so that an impassable barrier may be offered to the escape of the fluid.

*Münchener medizinische Wochenschrift, September* 5, 1905.

**The Treatment of Wounds with Ultraviolet Light.**—Axmann says that a certain amount of confusion has been introduced into the study of radiotherapy by the inexactness of various observers who have not been careful to differentiate between the effects and sources of heat, light and chemical rays. He warns against attempts to produce results by the use of variously colored light filters, and says that progress must be made by developing sources of light which shall produce rays of the sorts desired. He considers that the mercury vapor lamp is a very important advance, as it produces no red rays, but an excess of blue and ultraviolet rays. The visible portion of its spectrum extends only from 579 to 405 u. u., while two-thirds of the entire spectrum is made up of invisible rays running down to a wave length of only 253 u. u. The rays of this lamp have marked irritating, vaso dilating and bactericidal properties, and the author has used them with success in cases of alopecia, chronic eczema, acne, sycosis, erysipelas, etc. They also manifest a strongly oxidising action on venous blood, and the author describes very encouraging results obtained in cases of foot ulcers exposed to their action. He recommends a further application of the method to all open wounds or ulcerating surfaces, all of which are said to be greatly benefited by the active oxidation produced.

**Carcinoma of the Breast.**—Schinzinger reviews some of the evidence in favor of his proposal to perform double oöphorectomy as a preliminary to amputation of the breast in women who have not reached the menopause. He first made this suggestion in 1889, grounding his views on the observation that since carcinoma of the breast is always of especial malignancy in women who have not ceased menstruating, by prematurely bringing on old age the disease might be checked. Although this plan has not found many adherents in Germany or France, English surgeons have taken it up with more interest and have reported large numbers of cases in which the measure has appeared to contribute greatly toward prolonging life. In most instances the abdominal operation was not performed until the breast tumors had become practically inoperable, through recurrences, etc., but Schinzinger recommends the oöphorectomy just as soon as the diagnosis has been made. In this way the atrophy and contraction of the breasts that normally follow the menopause will be artificially induced, and in consequence the growth of the tumor be restricted. The author also believes that the tendency is to regard as inoperable many cases that are still susceptible of much relief and prolongation of life by surgical measures, and he considers that even the repeated removal of recurrences is to be advised. He concludes by describing four cases of carcinoma of the male breast.

*Deutsche medizinische Wochenschrift, August* 31, 1905.

**Prophylactic Nourishment in Laparotomy, and Puncture of the Intestine.**—Von Stubenrauch recommends the injection of a nutrient mixture into the intestine in all operations on the gastrointestinal tract, especially those involving the pylorus and upper part of the small intestine. The procedure consists in drawing a small piece of intestine, about one meter from the pylorus into the wound, puncturing it with a fine cannula containing a sharp trocar, and injecting the nourishment with a syringe through a long rubber tube attached to the cannula. The intestinal wound is then closed with Lembert sutures. The injected mixture is prepared from milk, eggs, salt, and sugar to which cognac may be added if stimulation is desired. By this operation the writer is enabled to administer nourishment immediately after operation, when administration per os is contraindicated. Postoperative intestinal paresis is thus guarded against by stimulation of peristalsis, while shock is also minimized. If it is anticipated that the patient will be unable to take food by the mouth for some days after operation, the intestine is sutured into the wound, which is partially closed, and then packed. After twenty-four hours a paste containing one per cent. sublimate is rubbed into the wound. Through this paste the intestine may be repeatedly punctured for the injection of nourishment as already described. Suture of the puncture wound is unnecessary. In cases of ileus in which a preliminary enterostomy is desirable the same procedure is followed, but the cannula is left *in situ* to drain off the glass and fluid intestinal contents. The operation is particularly indicated when the obstruction is due to inflammatory conditions in the pelvis.

**Observations on Radioactivity.**—Bergell recommended a method of fractional cooling for the quantitative determination of the radioactivity of mineral waters. If water containing radioactive substances is boiled on a return-flow condenser the water will become concentrated to a mineral quantity, but the emanation and other gases remain uninfluenced. These can then be condensed by liquid air, and isolated. Bergell further shows that less radioactivity is given off at 50° C than at a higher temperature. Practically this may be of importance in that through rapid cooling the loss of radioactivity in spring waters is materially reduced for a short time at least.

**The Treatment of Arteriosclerosis.**—Romberg emphasizes the importance of digitalis in all cases of arteriosclerosis in which there are evidences of muscular weakness of the heart. It is preferably given in small doses continued over a long period. Strophanthus is an efficient substitute. In the milder forms of angina pectoris, associated with cardiac insufficiency between the attacks, digitalis is often of service. For the accompanying asthma opium in some form is indicated. During the attack sodium nitrite or nitroglycerin subcutaneously is more satisfactory than the inhalation of amyl nitrite. In addition to digitalis laxative mineral waters are useful adjuvants in cases of arteriosclerosis associated with gastrointestinal disorders, diuretics in those associated with interstitial nephritis. In the latter group the high blood pressure is frequently lowered by the exhibition of small doses of digitalis. Empirically baths of moderate temperature containing a small amount of $CO_2$ have been found beneficial although contraindicated when the cardiac weakness is too marked. Within the same limits passive gymnastic exercises may be advised, but active movements involving a sudden increase of blood pressure are a source of danger. For the cerebral symptoms of arteriosclerosis Romberg advocates rest, a change of surroundings, the regulation of gastrointestinal functions and the internal administration of potassium iodide. Small quantities of nourishment should be taken frequently during the day, together with a sufficient amount of water. Digitalis may be used for the cardiac weakness unless a cerebral hemorrhage, however slight, has taken place. Sudden awakening at night with a feeling of anxiety is sometimes relieved by the immediate ingestion of a small amount of liquid or solid food. Secondary psychoses have a bad prognosis. The frequent vasomotor disturbances of arteriosclerotic subjects—intermittent claudication, erythromelalgia, etc.—should be treated by local baths, galvanic baths, and quinine. Extremes of temperature are to be guarded against. The general treatment coincides with that already outlined for cerebral complications. Internally, the most efficacious drug is potassium iodide combined with sodium bicarbonate given at intervals over a period of years.

*Deutsche medizinische Wochenschrift, Sept.* 7, 1905.

**The Value of Pavy's Method of Sugar Determination and Some Modifications of It.**—Sahli says that although in his book on clinical methods he criticised Pavy's method rather severely, he has since then come to a different conclusion regarding the value of the procedure, and now thinks very highly of it. The chief reason why it has not been more generally employed by clinicians and practitioners is owing to the incompleteness of Pavy's own descriptions, and Sahli has worked out what he considers an improved method of procedure which is so simple that he terms it the most suitable method for routine sugar determinations yet known, while it is second to none in point of accuracy. He discusses the theoretical and practical considerations involved at great length, and states that one cause of error has been Pavy's inexact directions for dilution of the ammoniacal copper solution. He has found that

if exactly 15 c.c. of water are taken to 5 c.c. of Pavy's solution there is no waste of ammonia or faulty reduction on boiling, and, furthermore, that it is not necessary to carry out Pavy's system of connecting the flask with the burette by rubber tubing, etc. The manner of boiling is also very important, for the fluid must be kept in gentle ebullition and no more, to avoid error. It is also preferable to perform the titration in a flask holding only 75 or 100 c.c. instead of 150 c.c., as Pavy recommends, as in this way the error due to exposure of the fluid to the air is reduced. A formula for making the reagent in two solutions, like Fehling's solution, is given, as well as many other details of manipulation which Sahli considers necessary in order to secure accuracy, and he concludes by expressing the view that the modified Pavy method is better for the purposes of the practitioner than even the simple fermentation test.

**The Examination of Pleuritic Exudates for Tubercle Bacilli.**—Zebrowski describes a series of observations he undertook in order to test the value of Jousset's method of examining pleuritic exudates for the presence of tubercle bacilli, which he called inoscopy. The principle of the method consisted in allowing the fluid to coagulate, with the idea that any suspended particles, such as bacteria, would be entangled in the meshes of the clot. This was then dissolved by the aid of an acid pepsin solution and smears made of the residue. In this way Jousset claimed to obtain 100 per cent. of successful results in cases that he examined for tubercle bacilli, but the author was less successful, and suggests that Jousset did not decolorize his preparations sufficiently. He has devised a plan of his own which is the exact opposite of Jousset's. Instead of favoring coagulation, he seeks to retard it by collecting the chest fluid directly in a phthorium sodium solution. The sediment forming on standing is collected and centrifuged, and the resulting deposit is used for the smears. At least 100 c.c. of fluid are required to insure success. The author examined thirty-six exudates and found bacilli in twenty-two of the number.

**Primary Erysipelas of the Larynx.**—Blum reports two cases of this rare condition. Both occurred in women and were accompanied by severe dyspnea, owing to stenosis, great tenderness to pressure over the thyroid region and the lymph glands, inability to swallow, and practically no changes in the pharynx. In the one case the fever was very slight, but in the other there was a considerable rise in temperature. The diagnosis was confirmed in both instances by the appearance of the disease about the face and head. The diagnosis is always difficult in the early stages as it simulates other acute laryngeal affections, especially diphtheria, closely, and the true nature of the disease is revealed only by its subsequent course.

*French and Italian Journals.*

**Ureteritis and Pyelitis.**—André Loumaigne sums up his thesis on this subject as follows: Ureteritis and pyelonephritis are of very frequent occurrence especially in women. In the great majority of cases clinical methods are sufficient to insure an early and positive diagnosis. The fact is most important, for it often offers the opportunity of preventing or at least of efficiently treating the renal infection. The original symptoms of uretero-pyelitis are urinary troubles, pain, and the determination of the presence of an indurated and painful cord which is the inflamed ureter. Of the urinary troubles, pollakiuria is of special importance, particularly when it is nocturnal. When micturition in the night is far more frequent than in the day, that is when there is absolute nocturnal pollakiuria, the diagnosis of pyelitis is certain. As to the symptom of pain, when it is located about the umbilicus, it has an almost irrefutable value. The direct palpation of the inflamed ureter is possible either through the anterior abdominal wall, or by vaginal touch. By the latter method, there is also often provoked the ureterovesical reflex, that is pain is associated with the desire to urinate. This reflex is of great importance in the diagnosis of pyelitis. The writer concludes by saying that nocturnal pollakiuria, periumbilical pain, and the ureterovesical reflex, clinch the diagnosis of ureteropyelitis.—*Revue Francaise de Medecine et de Chirurgie*, August 21, 1905.

**Acute and Chronic Cocainism Induced by Absorption through the Nasal Mucosa.**—H. Lemaire refers to the numerous applications of cocaine in rhinology, and emphasizes the inconveniences which may result from the too expensive or prolonged employment of certain preparations whose base is cocaine. He speaks of the phenomena of cocainism induced by absorption through the nasal mucosa, and distinguishes acute and chronic cocainism. The cardiac and circulatory disturbances are the most frequent. They consist of tachycardia without arhythmia, facial pallor and blanching of the skin, chilling of the extremities, and vascular spasms of the viscera which produce vertigo and vomiting. Psychical and sensory troubles are excitement, visual hullucinations, hypoesthesia of the extremities, and mydriasis. Respiratory disturbances consist of pain and sighing respiration. According to Pouchet, cocainism may be the point of departure for a latent neurosis. Chronic cocainism is like morphinism, observed in subjects who demand that the drug shall produce the same sensation of well-being and comfort that it did on its first ingestion. Cocaine is often taken in cases of coryza, rhinitis, and hay fever. The habit is rapidly acquired by the patient, who does not hesitate to intoxicate himself with it. Chronic cocainism causes both sensory and psychical troubles, chief among which are formication and itching of the extremities, severe pain and sometimes anesthesia. Visual acuity is lowered. Hallucinations of various kinds, cardiovascular troubles, anorexia, and cachexia are also observed.—*La Tribune Medicale*, August 19, 1905.

**Chronic Meningitis in an Heredity Degenerate.**—G. Doutrebente and L. Marchand believe that it is only too common in cases of degenerates, to attribute the mental abnormality solely to hereditary instead of searching for the possible cause in some disease of infancy or early life which may have caused cerebral changes. They report a case of mental deficiency in which not only hereditary unsoundness of mind but also infantile meningitis had a hand in producing the abnormal mental condition. The patient was committed to an asylum when he was ten years of age. The father had been an inmate of an asylum, being a criminal alcoholic. The child had in his first infancy given evidence of arrested development, both physical and mental. Intelligence was very rudimentary. There was an absence of all moral sentiments. Various attempts were made to educate him but were invariably unsuccessful. Death occurred at the age of nineteen years. At autopsy there was discovered the presence of chronic meningitis of infantile origin, localized in the anterior part of the upper borders of the cerebral hemispheres with a very accentuated atrophy of the frontal lobes. The meninges were soft and very thick, and underneath them were noted deep lesions of the cortex.—*Le Progres Medical*, August 19, 1905.

**The Hypophysis in Tuberculous Processes.**—B. DeVecchie and G. Bolognesi tells us that the tuberculous infection has no power to stimulate the function of the hypophysis: the course of the disease, the form and location of the tuberculous lesions have no action to stimulate the gland: on the contrary the parenchyma of the hypophysis appears to be at times in a condition of hypofunction. This condition of functional depression is not secondary to a hyperactivity, since the animals that are killed at a time soon after inoculation never show any modification of the chromatophile cells.—*La Riforma Medica*, August 19, 1905.

**Cystic Ureteritis.**—Eugenia Simelew after giving the history and histological examination of a case of ureteritis of a cystic nature gives us the following conclusions for future studies: 1. The formation of cysts on the mucous membrane of the ureter may be determined by a chronic inflammation of the membrane; at the same time, cystic ureteritis is a distinct morbid entity. 2. The cysts originate from the epithelial nests of von Brunn, and present the characteristics of cysts of degeneration: there is no parasitism in their etiology; the supposed parasites are simply products of degeneration of the epithelium. 3. The cysts are lined with epithelium, at first stratified, which later becomes flattened out until it has but one layer. 4. The masses of cysts on the ureteral surface originate in two ways: by a simple coincidence of cysts near together; or by the development of daughter from mother cysts. 5. The nests of von Brunn are normal epithelial formations, found in a certain number of individuals, representing invaginations of the lower strata of epithelium. 6. Elastic tissue is richly distributed in the walls of the ureters, but is not found in the cysts, because the walls of the ureter are profoundly altered, and the elastic fibers have disappeared.—*Il Policlinico*, August, 1905.

**Metabolism in Osteomalacia.**—Raffaele Caporali has selected from among forty-two cases of osteomalacia seen at the hospital in Naples, three cases of different types of the disease, and has studied the changes in their metabolism. The first case was one in the last stages of the disease, with intense pains, softening and fractures of the ribs, absolute immobility, presence of myelocytes and increase of eosinophiles in the blood, and reaction of Griess in the urine. The second was less serious, pain less, no fractures, capable of walking with support and with negative Griess reaction. The third had only slight pains in the chest, staggered in walking but needed no support, and her general condition was fair and blood composition normal. They were put on a strict diet for some days and the feces and urine collected, to estimate the amount of nitrogen,

phosphoric acid, and oxide of lime in them, as well as in the foods. The results of these researches are summed up thus: In all severe cases of osteomalacia there is a destruction of the body proteids, loss of phosphoric acid and of oxide of lime. In less severe cases these changes are less marked, while in the early stages they are not to be observed. The presence of myelocytes and increase of eosinophiles in the blood, and the reaction of Griess in the urine are of diagnostic value. The changes of metabolism bear no relation to the duration of the disease, but depend on its severity, and may occur in the early years. The tissues of the body all take part in the disturbances of metabolism, not the bones only, and the respiration and circulation are seriously affected.—*Archivio di Ostetricia e Ginecologia*, July, 1905

**Epithelioma of the Face and Its Treatment.**—Jeanselme declares that epithelioma of the face is of as much interest to the surgeon as it is to the physician, for if it is recognized in the early stages, intervention may prove entirely successful. Treatment ought to be energetic. As to the treatment of senile keratoses, the method indicated will depend upon the size of the lesion. If it is very small it can be easily removed with the curette and cauterized with the thermo-cautery. When it is large intervention would cause irritation and would transform it into a veritable cancer. As regards a papillary epithelioma, the only treatment is curettage and cauterization with a galvano-cautery. When the lesion is a torpid growth, but ulcerated like rodent ulcer situated in the upper two-thirds of the face, radiotherapy works marvels. This treatment may bring about complete cure. It must be very cautiously given, however, for if it is too intense it may cause radio-dermatitis, or superficial cutaneous inflammations, or even ulcerations, which, unfortunately, are very resistent to treatment, and which are very persistent often lasting for years and causing great pain. On the other hand, if the power of the rays is too week, the time devoted to their application is useless. In dealing with cancer of the lips, radiotherapy nearly always fails. Excision of the growth, and the ganglia as well, is indicated in such cases. This treatment is often followed by the use of radiotherapy. In those cases which formerly have been treated by the application of arsenical caustics, the writer believes that radiotherapy will prove the method of choice in the future. In cases of epithelioma the physician should not forget the importance of soothing the pain attendant upon this disease. This is best accomplished by the administration of opium, which this class of patients can bear especially well.—*La Médecine Moderne*, August 30, 1905.

**Injections of Gas for the Pain in Neuralgia.**—Desplats has found that the injection of gas is very efficacious in cases of neuralgic pain. The object of this treatment is to distend the subcutaneous cellular or the deep interstitial tissue. This action is successfully attained by the use of air, Desplats' experience with irritating or sedative vapors having yielded only negative reslts. The bulb of a thermocautery and a Pravaz needle are the only apparatus required. The bulb is worked rapidly until the reservoir is filled with air, which is then gradually injected into the cellular tissue. A little massage of the injected part will displace the air. Any region seems to be amenable to this treatment. The course of the air through the tissues can be watched when the injection is subcutaneous. In some cases the diffusion is vascular, the air spreading with great rapidity along the length of the vessels. Relief quickly follows the injection, which is always painless, though sometimes several hours elapse before the pain ceases, but relief is sure to come. Generally, one injection is sufficient, but in severe cases sometimes two or three injections at different points are necessary. These air injections, although first employed in cases of neuralgia, have given the best results in cases of sciatica, intercostal neuralgia, lumbago, certain arthralgias, and acute affections of the lungs and pleuræ.—*Revue Française de Médecine et de Chirurgie*, August 28, 1905.

**Dangers of Contagion in the Sanatorium.**—Ch. Malibran and L. Gassot, in replying to the criticisms aimed against sanitoria, emphasize the fact that in a well-organized sanatorium the risk of contagion is less than in any other place where tuberculous patients live. The great factor in the propagation of tuberculosis is the expectoration. Koch's bacilli are scattered through the atmosphere—it may be by powdered sputum after it is dried, or it may be by liquid particles which are projected by coughing. In the sanatorium the employment of spittoons holding a liquid antiseptic prevents desiccation of the sputum, and so destroys the principal source of infection through the air. Very little danger attaches to the liquid particles projected by coughing. In the first place, such particles remain for a short time only suspended in the air, and the daily cleansing of both walls and floor with antiseptics removes any germs that may have settled there. There is also almost no danger to be feared from personal contact. However, in order to do away with the least risk, the various types and degrees of the disease can be separated. From long observation it is known that both visitors and attendants escape contamination. The most careful hygienic measures are taken in every particular to promote the safety of the inmates. These authorities believe that no fear of danger should keep a patient away from the advantages which are offered to the tuberculous sufferer in the modern sanatorium.—*Revue Française de Médecine et de Chirurgie*, August 28, 1905.

**Exploratory Puncture as a Means of Diagnosis in Gynecology.**—Pietro Gioelli publishes forty-three cases in which exploratory puncture was used as a means of diagnosis in abdominal conditions, such as pelvic peritonitis, diseases of the adnexa, and pelvic abscess. The fluids removed were examined and served as a means of accurate diagnosis. The author gives us his conclusions: (1) Abdominal puncture is harmless when made with due precautions: the examination of the fluid obtained is of great diagnostic value in many cases. (2) In exudates, especially of long standing, microorganisms are not found, or they are of slight virulence. (3) The gonococcus is most frequently found. (4) In pelvic peritonitis with fetid odor, this odor is due to anaerobic bacteria, or pathogenic aerobes, which are highly virulent. (5) In cases without fever or microorganisms the fluid will not be reabsorbed, but operative evacuation will be necessary.—*Archivio di Ostetricia e Ginecologia*, July, 1905.

**Lymphangioendothelioma of the Processus Vaginalis.**—Santi Rindone reports this case of endothelioma of the processus vaginalis, not involving the testicle, as an exceptional condition. There are in literature various cases of endothelioma of the serous membranes, but none of the serous structure of the testicle. The patient had, as early as the eighth year, a tumor in the scrotum which was thought to be a third testicle. It increased gradually in size, but never gave him any pain or other trouble until it had been in existence for thirty-four years. It then enlarged rapidly, became painful, produced fever and enlargement of the inguinal lymphatics. It was removed, but recurrence occurred in the lymphatics and caused the death of the patient. As soon as the tumor lost the character of benignity the patient had fever, and this disappeared with the operation, but recurred when the tumor grew again in the lymphatics. The tumor was a typical endothelioma, with a basement substance forming alveoli and cellular masses.—*Giornale dell'Associazione Napolitana dei Medici e Naturalisti*. Anno XIV, No. 3.

**The Insufflation of Oxygen Into the Abdominal Cavity in Sepsis Following Laparotomy.**—Romolo Costa reports two cases of sepsis after laparotomy, in which oxygen was insufflated into the abdomen when septic occurred. The first was after an operation for extrauterine pregnancy. On the third day symptoms of sepsis came on. The abdomen was reopened and washed out with normal salt solution, and a drainage tube was inserted, through which the oxygen was blown into the cavity, so as to distend the walls. The improvement in the patient's condition was immediate and permanent. The second case was after rupture of the uterus in a very long labor. The use of oxygen gave no improvement and the patient died. The use of oxygen in itself is harmless, and experiments on animals showed that its use in infections by the colon bacillus was of value.—*Annali di Ostetricia e Ginecologia*, July, 1905.

---

**The Feeding of Atrophic Nurslings.**—G. Variot gives Jégourel's definition of this affection: "Infantile atrophy is a hindrance of growth in both weight and size more or less pronounced and prolonged, arising from gastrointestinal troubles. Its degree may be determined by comparison with the weight and size of a normal child of the same age." The writer has given much careful study to these cases, and he has come to the conclusion that there is no absolute rule for determining the rations in atrophic cases. He states that the study of calorification gives no thoroughly reliable indication of the needs of the individual case. He is convinced that experience is the best guide to a knowledge of the limits of gastrointestinal tolerance. At a later stage the weighing machine is the best guide. The physician must proceed by tentative research, investigating the tolerance of the stomach and the intestines, judging the nourishing value of the milk by the careful and systematic weighing of the child, and by following its growth step by step. The curve of growth varies according to the degree of atrophy. In the case of athrepsics the curve is practically a horizontal line for one or several months. It has a tendency to decline, ending in death. In cases in which the degree of atrophy is slight it is common to note that the infants become quite vigorous in their second year. These cases require the greatest patience.—*The British Journal of Children's Diseases.*

## AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

*Eighteenth Annual Meeting, Held in New York City, September 19, 20, and 21, 1905.*

PRESIDENT, DR. HOWARD W. LONGYEAR, OF DETROIT.

AFTER the delivery of an address of welcome by Dr. George B. Fowler, which was responded to by Dr. Charles A. L. Reed, the reading of papers was begun.

**Multiple Pregnancy Complicated by Double Pyosalpinx.**—Dr. O. H. ELBRECHT, St. Louis, Mo., read a paper with this title and reported an interesting case in detail. The most striking feature of this case was the obscurity of this rare complication, for without the autopsy he would certainly have abided by his first and only antemortem diagnosis, *i.e.* sapremia, and would have continued to believe that the general peritonitis was the result of the sapremic infection traveling upwards through the tubes and thus into the abdominal cavity, for such a process, to his mind, would be all the more plausible in the large and flabby uterus of multiple pregnancy, more especially from the fact that large blood clots were passed on the first day, showing the relatively imperfect contraction of the uterus. The case also showed very plainly the ability or the degree of tolerance of the pelvic peritoneum to cope with infections, as it was the author's opinion that the peritonitis was not general until the sixth day, for up to that time there was no hiccoughing, no vomiting, no abdominal distention, and no apparent weakness. Another deduction was that gonorrheal peritonitis, while not very dangerous, if confined to the pelvic peritoneum, was surely dangerous when it crept out of the pelvis and became diffuse. It was also his firm belief that the pyosalpinx in this case was unilateral at the time of impregnation, and that the infection was transmitted by the escape of virulent pus to the open fimbriæ of the unaffected side. The only cases he could find analogous to his had been reported by Hare and Talley. The reports of two pathologists in the speaker's case, who worked independently of each other, both showed that the tube, which was secondarily infected, was infected by way of the fimbriæ, as its pathology was confined entirely to its outer third; the middle third showed only slight inflammatory changes, and the inner third, including the uterine attachment, was normal. Blank had advanced the theory that virulent bacteria in the tube had a tendency to induce pyosalpinx during pregnancy by reason of the hyperemia. He further stated that fifty per cent. of those cases in which the tubes were adherent in the cul-de-sac ruptured as pregnancy advanced, from tension, pressure, or from stretching of the adhesions, which forced pus out of their fimbriated extremity. The experience of the author with three cases of this class substantiated Blank's theory. These three cases were reported.

Dr. CHARLES A. L. REED, Cincinnati, Ohio, said that this case, with the pus tube undetectable, only added one possible condition that pointed to the reason why the class of cases under discussion should not be subjected to operation earlier and more radically than they had been heretofore. With a double pus tube with antecedent conception, it followed that the deduction of the essayist, that the infection of the tube was unilateral prior to impregnation, was absolutely incontestable. As to infection on the other side, the probability was that it resulted from a progressive invasion of tissue, the mucous structure serving as the nidus of infection occurring within the uterus following delivery.

Dr. HERMAN E. HAYD, Buffalo, N. Y., was inclined to believe that many cases of pyosalpinx complicating delivery were seen that were due to a latent gonorrhea existing in the tube, which sprang into activity as a result of the trauma incident to labor.

Dr. CHARLES L. BONIFIELD, Cincinnati, Ohio, believed many cases of double pyosalpinx cleared up sufficiently to allow the patients to become pregnant. In years gone by he had informed patients they would never become pregnant when he detected a mass on each side and there were further evidences of pyosalpinx, and on a few occasions he had been deceived after six, eight, or even twelve years, the pus having become absorbed and the women having become pregnant. He cited a case that came under his observation many years ago of double pyosalpinx, or he thought it was such. The woman refused operation. Everything in the pelvis was matted together. She gradually got better, and at the end of six or eight years (he could not remember the exact time) became pregnant, and he delivered her. She passed through labor smoothly, but at the end of a week she suddenly raised up in bed and dropped over dead.

Dr. RUFUS B. HALL, Cincinnati, Ohio, did not believe that a woman with double pus tubes could afterwards become pregnant. If such a woman should become pregnant he would have some doubt as to the diagnosis of bilateral pyosalpinx.

Dr. JOHN YOUNG BROWN, St. Louis, Mo., thought the mere existence of pregnancy in the case reported by the essayist precluded the possibility of the woman having had bilateral pyosalpinx. The pathology, as revealed by the autopsy, showed conclusively that the case was one of unilateral pyosalpinx, which had lain dormant and was kindled by the trauma of labor, and that the leakage from the pus tube produced the diffuse peritonitis, and the condition found on the other side was due to bathing this side with the pus that was produced by the peritonitis.

Dr. JAMES F. BALDWIN, Columbus, Ohio, had not had a case of double pyosalpinx followed by pregnancy, yet he thought it might occur.

Dr. LEWIS S. MCMURTRY, Louisville, Ky., said that abdominal section in a puerperal convalescent was a very serious procedure. The operation of vaginal incision and drainage, so enthusiastically advocated by Pryor, would accomplish very little in a case like the one reported from the standpoint of therapeutics; hence, in this case we had a very valuable addition to the scanty literature of the subject as to the possibility of pathology of the tubes connected with puerperal disease, and a very valuable guide to operative interference.

**Some Considerations on the After-Treatment of Abdominal Sections.**—Dr. WALTER B. CHASE, Brooklyn, New York, stated that in reviewing his personal experience he was led to the conclusion that the principal, and by far the most frequent, condition after laparotomy requiring treatment was flatulence. The accumulation of gas in the intestinal tract was present, to a greater or less extent, in a majority of cases. The principal causes were reversed peristalsis, intestinal paresis, and the effect of the anesthetic itself. He seldom gave anodynes except in conditions of pain, making a possible exception in cases when peritonitis was present prior to operation, or other structures involved in the operation were so friable that peristalsis should be prevented for a time, or in cases following intestinal anastomosis. Its administration for the relief of pain was admissible and perhaps mandatory. It was a matter of much moment when anodyne was selected. Ordinarily he used codeine hypodermically in doses of one-fourth to one-half grain, or more, if required. While its power to relieve pain and check peristalsis was much inferior to that of morphine, its lesser disturbance of the nervous system, checking of secretion and tendency to undue constipation made it an agent of great value. It was imperative that a reliable preparation be used. In troublesome cases of continued nausea the administration of small doses of cocaine, gr. 1-10 to 1-12, exercised a salutary sedative influence on the nerves supplying the stomach, and was attended with happy results. Either the nausea or flatulence, or both, might disappear in a few hours after operation. Among the newer remedies for the relief of intestinal paresis was the alkaloid of the calabar bean. Salicylate of physostigmine, given in doses

of gr. 1-100 to 1-50, or even more, hypodermically, repeated once in four hours, seemed to induce a powerful contraction of the circular fibers of the intestinal tract. The diet of patients after abdominal section called for the greatest circumspection always following the rule that nourishment, taken per orem, before the stomach retained or digested it, was positively harmful. When shock was profound, minute doses of morphine sulphate were among the most powerful stimulants, and superior to most for prompt and sustained effect. The author discussed at length the importance of bodily temperature and position of the patient after laparotomy.

**Some General Principles in Conservative Pelvic Surgery.**—Dr. JOHN F. W. WHITBECK, Rochester, N. Y., said it was decidedly advantageous to have a general knowledge and a general experience before making use of special methods in the treatment of pelvic disorders. Medical and mechanical means should be tried in suitable cases before resorting to surgical intervention. Only diseased organs should be removed. Sound organs and normal parts of unhealthy organs should be preserved. Conservative plastic surgery should be employed to save such organs as could be made to functionate or to serve some useful purpose. Diseased organs should be removed in the order of their pathological precedence and importance, with a view to benefit the patient by promoting her comfort and prolonging her life, even if a perfect cure was not to be expected.

**Trivial Pathological Conditions of the Uterus and Adnexa Considered as Causes of Severe Gastric Disturbances.**—Dr. FRANCIS REDER, St. Louis, Mo., stated that during the last two years eight patients had come under his observation, six of whom presented a train of symptoms that would ordinarily be grouped as those of hysteria or neurasthenia, moderately severe in character, the two remaining patients being free from any such pronounced neuropathic phenomena, and some in fairly good health, with the exception that their stomachs were weak. The pelvic organs of these patients upon examination gave evidence of disease, and although the examination did not reveal anything of a serious nature, still local minor operations afforded relief. In the cases cited by the author it was a surgical procedure that anticipated the pathological conditions. In the opinion of the author, to wait for pathological conditions to give evidence of their existence by more pronounced local symptoms in gynecological disease, where there was a marked reflex neurosis, would be to invite secondary conditions that might prove of a very grave nature.

Dr. RUFUS B. HALL, Cincinnati, Ohio, thought the cases reported had pathological conditions sufficiently marked to justify operation regardless of their neurotic condition. To cure nervous patients it was sometimes necessary to remove every obstacle in the way of perfect health physically. He was convinced that if many of these cases had not been operated upon, their condition would have become worse, a more grave pathological condition would have resulted later, and it would not only have been more trying for the patients, but rendered the surgery more difficult and harder for the patients to recover from the operations.

Dr. X. O. WERDER, Pittsburg, Pa., was not enthusiastic about operating on neurotic patients, as the results were not usually good, and he feared the essayist would have some of the patients upon whom he had operated return to him in a few months with the same symptoms for which they had previously sought relief.

**Prolapsus Uteri and Its Treatment.**—Dr. HERMAN E. HAYD, Buffalo, N. Y., spoke briefly of the various conditions which contributed to the production of prolapsus uteri, and then discussed its treatment by surgical means only, and according to the degree of descensus and the necessity for the preservation of the uterus, the operative treatment was carried out. He believed that in minor degrees of prolapsus uteri, with rectocele and cystocele, the Alexander operation, with well-directed plastic surgery of the vagina and perineum, would cure these simple forms. When the prolapsus extended to the introitus, or the cervix pointed through the vulva, a vaginal hysterectomy, with a well-performed anterior and posterior colporrhaphy and a perineorrhaphy accomplished the best results; and the effect was permanent if the vault of the narrowed vagina was sewed firmly to the cut edges of the broad ligament. When it was desirable to save the uterus for the purpose of childbearing, or to continue the function of menstruation, the cervix must be amputated and an anterior and posterior colporrhaphy and perineorrhaphy must be done, and the uterus firmly ventrofixed to the abdominal wall through a median abdominal incision. Usually all these operations could be performed at one sitting, but if it was desirable to make two operations, the posterior colporrhaphy and perineorrhaphy must be done at the second time, say three weeks after the first operations. The author, however, preferred the removal of the uterus, as this operation had been infinitely more successful in his hands. He also deprecated the performance of all operations which closed the vagina, as he believed this was unnecessary, and because he had seen much unhappiness result from this procedure. For the extreme cases of pelvic hernia, he was particularly pleased with a reprint sent to him by Dr. Crile, in which he advocated a very elaborate and extensive operation. For one such case, which occurred in his own practice, he sewed the united vagina and broad ligaments to the abdominal wall, and the result was very satisfactory. However, such extreme measures were seldom called for, as most cases could be cured by the other operations described. Dr. Hayd then described his operation upon the posterior vaginal wall and the perineum, in which he cut out a large triangular piece of the posterior central part of the vagina, and then, with the finger in the rectum as a guide to make tense the obturator fascia and elevator ani muscle, he sewed these two opposing surfaces or structures in perfect apposition, with fine chromic gut, which layer of sutures was buried by bringing together the vaginal mucous membrane by another layer of sutures, and finally the skin was brought together by silkworm gut. This operation lessened the size of the vagina and lengthened it by producing an oblique canal instead of a horizontal one, and by carefully proximating the fascia and levator ani, the *sine qua non* of all perineal operations, the result remained fixed and permanent.

**Surgery of the Liver.**—Dr. WILLIAM J. GILLETTE, Toledo, Ohio, read a paper on this subject in which, after discussing the control of hemorrhage, the power of the liver to regenerate itself, infection and cholemia, he described a means of controlling hemorrhage from the liver in certain cases of severe bleeding when the blood vessels cannot be easily reached. It sometimes happened that to tie them required a further enlargement of the lacerated liver substance. This of itself increased the gravity of the patient's condition. Three years ago he was called in haste to see a young girl of fourteen years who had been shot by a target gun, the bullet entering between the eighth and ninth ribs, near the costal cartilage, and passing through the right lobe of the liver and lodging behind the stomach. The low velocity of the bullet had caused it to make a tear rather than a perforation. When first seen the patient was nearly pulseless, and manifested all the evidences of a severe internal hemorrhage. Her face and lips were white and bloodless. The abdomen was opened. An incision was made close and parallel to the costal cartilages on the right side. The abdomen was found full of blood, which could be seen freely oozing from the torn liver. He attempted to control this first with cat-gut ligatures, but the friability of the tissues prevented it. Some time previously he had had an experience with a similar wound of the liver made by a bullet, and had attempted to control the hemorrhage by packing with gauze; but the patient, a strong, robust man, promptly died from the continued loss of blood. Post-mortem examination revealed that the gauze packing had been entirely inadequate to control it. Having this case in mind, he did not feel like trusting to gauze again, and in-

asmuch as it was not controlled by direct ligation, it occurred to him that by passing sutures from within entirely through the liver substance and through the abdominal wall, making exit between the ribs after the manner of a staple, and tied firmly on the cutaneous surface, that permanent and constant pressure could be made sufficient to control the hemorrhage without the ligature cutting into the friable liver tissue. Five or six such sutures were now introduced on the proximal side of the wound, each one embracing about three-quarters of an inch of the liver substance. Care was taken to link them together so as to include all the bleeding tissues in their bite. The ligatures emerged between the ribs the same distance apart as they were entered on the liver substance, and when firmly tied all the hemorrhage and oozing ceased at once. Other injuries to the viscera, which were slight, were repaired, a drainage tube was inserted, and the abdomen closed. The patient made an uninterrupted recovery. He had since used this method in two cases, in one of which, in removing a very adherent gall-bladder, he met with a severe hemorrhage which was readily controlled with it. Recovery was prompt. The third case was one in which an hydatid cyst, the size of a small cocoanut, was removed, together with a large number of gallstones, from a suppurating gall-bladder. This patient unfortunately died from peritonitis a few days later, but the hemostasis was perfect. The author referred at length to the more recent contributions to the surgery of the liver.

**Papillary Cystadenoma of the Breast.**—Dr. Edward J. Ill, Newark, N. J., contributed a paper with this title and said that this disease was comparatively rare, but that he had seen eight cases in his practice. There was very little literature concerning the disease. Its characteristic symptoms were a clear yellowish pink to dark-bloody discharge from the nipple. On palpating the breast a small tumor could be made out early in the disease which might become multinodular later on. He had observed cases from a few weeks to eleven, twelve, and twenty-one years. The pathological condition found was a papillary adenomatous mass projecting into the milk duct. It was nonmalignant in character. The patient might get well without any interference. When the disease persisted, he advised removal of the breast.

Dr. Miles F. Porter, Fort Wayne, Ind., said that cystadenoma of the ovaries and of other organs was prone to become malignant, and no man could tell whether the tumor was malignant or not until he had removed it and had carefully examined it. Some of these tumors were pronounced to be nonmalignant by microscopists, yet there was recurrence after their removal. Again, others that were pronounced malignant and operated upon recurred.

Dr. Joseph Price, Philadelphia, Pa., had never regretted the early removal of tumors of the breast, for fear that they might become malignant. He cited interesting cases in point which illustrated the importance of early operation.

Dr. Gunther, in closing the discussion for Dr. Ill, said that these patients were not aware that they had a tumor. If they had one it was very small. There was no involvement of the axillary glands, and they sought medical advice principally on account of the discharge mentioned from the nipple. The history and symptoms in these cases were sufficient to exclude malignancy.

**The Byrne Operation and Its Application in the Radical Treatment of Cancer of the Cervix.**—Dr. X. O. Werder, Pittsburg, Pa., in a paper on this subject described the operative technique employed by Byrne, and said that Byrne placed special stress on the importance of thorough and repeated cauterization of the wound surfaces and edges from which cancerous tissue had been removed, regarding it as the best safeguard against a recurrence of the disease. The most remarkable feature of the Byrne operation, when compared with all other operations undertaken through the vagina for the cure of cancer of the cervix, and one which seemed to justify Byrne's conclusions, was the almost uniform absence of local recurrence. While employing the method described by Byrne in his first cases, he invariably followed it by the ablation of the remaining portion of the uterine body and appendages. Subsequently, however, he simplified the procedure very materially by dispensing with the preliminary amputation of the cervix. The principal features of the Byrne operation had been retained, namely, thorough and repeated cauterization of all wound surfaces and edges. The operation differed from the usual vaginal hysterectomy by the use of the cautery knife for detaching the cervix from its vaginal connections; the application of the electrothermic clamps devised by Downes, and the final cauterization of the stump with the dome-shaped cautery. Dr. Werder described the technique as he employs it at the present time as follows: "The cervix is curetted with a heavy, sharp spoon curette until all necrotic tissues are removed, and the bleeding surfaces cauterized until all oozing is controlled. The cervix is then firmly held with volsella forceps and an incision is made entirely around the cervix at a considerable distance from the affected area by means of the cautery knife, keeping it at a dull heat and never turning on the current until the knife is placed against the tissues to be burned. In this manner no oozing will take place and the parts will remain perfectly dry. While making traction upon the cervix the dissection is carried up carefully between the bladder and uterus, an assistant with a retractor drawing the bladder wall away from the hot knife. With the aid of the index finger the peritoneum is then reached and opened with a blunt scissors. Douglas' pouch is opened posteriorly in the same manner and the lateral vaginal attachments are burned through. The bladder is then widely separated from the uterus and broad ligaments by inserting the index fingers of both hands with the palmar surfaces directed towards both pelvic walls and making firm lateral traction. The fundus uteri is then seized with vulsellum forceps and dragged down into the vaginal outlet, while a broad retractor in the hands of an assistant holds up the bladder against the symphysis pubis and well out of the way during the subsequent steps of the operation. Pads are now introduced into the pelvis to hold back and protect the abdominal contents. Ordinary heavy clamps are then applied to the whole broad ligament, first one one side, two usually being required on the other side. The same procedure is then repeated on the other side and the entire uterus and appendages removed. Thus far the operation differs very little from the old clamp method of vaginal hysterectomy, excepting that all incisions have been made with the cautery knife. After packing off the pelvic cavity very carefully with gauze pads, the upper clamp on the infundibulopelvic ligament is seized, the ligament put on a stretch, and a Downes electrothermic clamp applied externally to it, protected by the shield and additional pads, if necessary, and the tissues included in the forceps are then thoroughly cooked until a good ribbon is obtained. The Downes' clamp is then removed, the ribbon cut through near its inner edge, and if, after a few moments, no bleeding occurs, dropped. The next clamps are then treated in exactly the same manner until both ligaments and all other uterine attachments have undergone this cooking process." Of the sixteen cases operated upon by Dr. Werder only one patient died, about four weeks after the operation, from uremia. She is supposed to have suffered from nephritis for ten years previously. The operation, he thought, might have hastened, but not caused, her death.

**Indications for Hysterectomy in Puerperal Septicemia.**—Dr. Charles Greene Cumston, Boston, Mass., stated that hysterectomy applied to the treatment of acute puerperal infection was as yet a mooted question as far as its indications were concerned, and it would be quite as illogical to advise this interference in all serious cases as it would be systematically to condemn it. All surgeons seemed to be in accord as to the great difficulty of formulating the indications for this operation, and especially the time when these became formal. To come to a conclusion all clinical methods of examination and those of the laboratory must be employed. The latter, however, were far from being of

equal value, as no positive result could be obtained from a bacteriological examination of the lochia or blood. Cytological examination of the blood would give excellent data as far as the prognosis of the type of infection was concerned. Clinically, there was no one valuable sign; but taken altogether the symptoms obtained by careful intrauterine examination might indicate the necessity for surgical intervention when all other therapeutic procedures had failed. Septicemia occurring at once after labor could not derive benefit from surgery, but, on the other hand, it would appear that hysterectomy was indicated in cases of secondary septicemia with a slow evolution, or those taking on a pyemic type proceeding by successive stages, on the condition that there were no visceral metastases, in which case surgical treatment would be the method of exception.

**Abdominal Hysterectomy for Multiple Fibroids Complicated by Pregnancy.**—Dr. J. HENRY CARSTENS, Detroit, Mich., read a paper on this subject in which he reported the case of a woman, 42 years old, who was never pregnant before. The tumor had been noticed for five or six years, but was not accompanied by hemorrhage. Menstruation was regular until May; there was a slight show in June and July. He operated upon the woman in the middle of August and removed the tumors. The growths became rapid during the last three months. The patient made an excellent recovery from the operation. These cases were not uncommon, still they were sufficiently rare to warrant reporting them. In nearly all cases the women were sterile; a growth developed, and after some years they became pregnant, which prompted one to suspect that there was some abnormal condition of the uterus, perhaps some malposition, which prevented impregnation, but as the result of the presence of the growth the uterus was pulled up or pushed over in one direction or another in such a way that the ova could pass into the uterus and cause pregnancy to take place. This seemed to him to be the correct explanation of the occurrence of pregnancy in sterile women after the development of fibroids. In reference to general rules for such cases, the cases varied so much that no definite rule, he thought, could be laid down to govern all of them, but on general principles he thought cases of fibroid tumors complicated by pregnancy could be left alone if they were subperitoneal and located in the upper half of the uterus. Fibroids, however, located in the lower half of the uterus or in the broad ligament should be removed. Fibroid tumors that were adherent or complicated with other pelvic diseases should be removed by enucleation, or in some cases an abdominal hysterectomy should be performed.

**Personal Experiences in Myofibroma of the Uterus.**—Dr. MILES F. PORTER, Fort Wayne, Ind., presented some of the more important facts gained from the treatment and observation of over 125 cases of myofibroma of the uterus. The earlier cases having been seen during a rather exacting general practice, and many of them operated upon away from home, in private houses, without adequate assistance, accounted for the fact that the records of this part of the author's work were imperfect. Of the 125 cases more than 100 were subjected to supravaginal hysterectomy. Two vaginal hysterectomies were done in which the abdomen was entered. Myomectomy through the abdomen was done six or eight times only, except cases in which small fibroids were removed during celiotomy for other causes, and these were not considered. Hemorrhage was not so prominent a symptom as was so generally thought. In two cases this was the immediate cause of operation, and in one it manifested itself first after establishment of the menopause. Pain, especially during the menstrual period, had been the most common symptom. Only one case of pyosalpinx as a complication was seen. In one an eight and one-quarter pound tumor was removed from a four and one-half months' pregnant uterus. Normal labor at term followed, and one child had been born to the mother since without accident. In one case the pregnant uterus was removed for pain on the theory, which the specimen proved correct, that the woman could neither miscarry nor carry the child to term. The third was operated because of mild sepsis due to retained fetus. Both recovered. He said the women with fibroid tumors were peculiarly liable to infection following labor, miscarriage, or menstrual flow. In several cases this danger was the chief indication for operation. Three cases were reported to support this opinion. The rapid growth of fibroids during pregnancy was believed to be more apparent than real. Partial or complete sterility was common in fibroid patients. But one case of malignant degeneration was seen. But one patient died. This was due to the breaking down of a large vaginal tumor coexisting with a large abdominal tumor. Both were removed through the abdomen. The removal of the vaginal tumor per vaginum by morcellation, and an abdominal hysterectomy later, he thought, might have saved the patient, who died from the effect of the sepsis from which she was suffering at the time of the operation, combined with the effect of the shock and loss of blood. One case of dermoid of the ovary with multiple fibroids was met with, one practically a pure myoma, and one fibroid of the ovary complicating fibroid of the uterus. Oöphorectomy for fibroids was not a justifiable operation, as it neither stopped the hemorrhage nor the growth of the tumor. The ideal operation for myofibroma would leave the genital tract intact, or as nearly so as possible within reason. The tubes should always be removed when operation rendered pregnancy impossible. Healthy ovaries should be left, as should healthy cervices. Whether to operate through the vagina or through the abdomen might be determined before the operation was begun, but the details of the technique should be developed as the operation proceeded. In rare cases the elastic ligature was of service. Twice the bladder was cut, but was immediately repaired, and no harm resulted. One case had a hemorrhage from a split of the broad ligament, which occurred the night following the operation as a result of the patient starting violently during a dream. No trouble from silk as ligatures was experienced, but because of the evidence against it, catgut was substituted as soon as he had learned to sterilize the latter by heat. The death rate of abdominal operations need not be over two per cent., and vaginal operations involving the peritoneal cavity should not be above one per cent.

**Unusual Dilatation of Cornual Blood-Vessels, with Rupture Into the Uterine Cavity; Hysterectomy, Followed by Recovery of Patient.**—Dr. FRANK F. SIMPSON, Pittsburg, Pa., reported an interesting case, and said that apart from their association with neoplasms, vascular changes were not infrequently found when persistent bleeding occurred near the menopause. Arteriosclerosis was rather common; but aneurysm, aneurysmal varix, and varicose veins occurring within the myometrium were rare. In this case there was an excessive vascularity of the uterus, with sclerotic arteries and varicose veins. The sclerosis was found in its several forms, varying from a slight nodular infiltration of the intima to complete obliteration. In addition, we had the unusual spectacle of greatly dilated varicose veins which were the subject of repeated spontaneous rupture, with repeated spontaneous closure. In the author's case there was a clinical picture which portrayed the perils of this disease in its most serious form. In the well marked cases that had come under his observation arteriosclerosis of the uterine vessels had been accompanied by menorrhagia and metrorrhagia, which began between the ages of 38 and 45. The bleeding became more and more pronounced, had resisted medicinal and minor surgical measures, finally endangered life, and had yielded only to hysterectomy. In this case, however, the first symptom was a furious hemorrhage due to the rupture of a large varicose vein into the uterine cavity. Within two months three other hemorrhages burst upon the patient without warning, and each imperiled her life. The gross pathological findings made it clear that without surgical intervention hemorrhage or infection would inevitably have closed the scene within a short time.

(*To be Continued.*)

## AMERICAN ASSOCIATION OF LIFE INSURANCE EXAMINING SURGEONS.

*Sixth Annual Meeting, held at Portland, Oregon, July 10, 1905.*

Dr. Denslow Lewis of Chicago, President.

**Requirements for Special Instruction of Medical Students in Methods of Examinations for Insurance.**—Dr. W. B. Cluness of San Francisco in this paper discussed the fact that life insurance companies too often are the victims of errors due to ignorance on the part of recent graduates. Teachers should be impressed with the importance of instructing students in the methods of diagnosing disease in its incipiency. He attached much importance to tact and discernment, which sometimes count more than eminent ability. The speaker believed that the physician not less than the clergyman and lawyer should have an all-round training, making him a fit associate for people of education and culture. He would have students taught that life expectancy was the principal feature in life insurance problems, and that there was constantly going on an adverse selection against the company which it was the duty of the medical examiner to minimize to the extent of his ability, and that heredity and environment were the principal elements which determined the longevity of individuals. Students should be taught to give the company facts and not generalities. They should be urged to have the courage of their own convictions, and to report their findings.

Dr. Henry Wells Dewey agreed that instruction in college for this special work ought to be encouraged. The student should be given opportunities to observe normal conditions as well as pathological.

Dr. H. G. Brainard of Los Angeles defined the positions of the applicant for insurance and of the patient in the office in their different aspects. The latter, he said, gave many points about himself; the former, knowing that any pathological condition would cause a higher rate of insurance, tried to prevent such disclosure. This different plane of examination he thought should be impressed upon the medical student.

Dr. D. W. Smouse of Des Moines thought the matter should be reached in some practical manner, and suggested the sending of a letter to the respective medical schools of the country to this end.

Dr. William T. Amos of Portland thought it possible that many applicants were approved by young physicians because of the persistence of the agent, and because the young physician needed the money. The young men felt that they were getting no real support from the home office and consequently disregarded the instructions of care in the matter of risks.

Dr. Cluness in closing said that he believed the trouble lay in the lack of instruction in the medical colleges in this special department. He felt strongly that the importance of the students' positions as medical examiners should be instilled into their minds during their college career.

**Collision or Collusion.**—Dr. William T. Amos of Portland explained his reluctance in writing on a subject which seemingly criticised the insurance companies for which he examined, but in consideration of the conditions he felt it was to the best interest of all concerned that the matter be brought up of the non-support of the local examiner by the medical directors, which resulted in collision between the agent and examiner, with the working of injustice to the examiner, or a collusion between the agent and examiner, with the working of hardship upon the company. He analyzed the modus operandi by which this collusion grew unconsciously to the examiner between the agent and the examiner. He hinted at the great desire of the insurance companies to get business, good business if possible, but business anyway. He intimated that the medical directors in their instructions to the local examiners cautioned them to be careful to a degree to which they did not expect the examiners to conform. He spoke highly of his opinion of the integrity of physicians as a class, but could not see how they could be blamed for receding from the high standing supposed to be set by the medical directors when they saw the easy examiners getting all the business.

**We Can Do Better Work for Our Companies; Do They Want It?**—Dr. William Moore of New York City spoke of the chief causes which prevent the companies from obtaining the best services of the medical examiners, and the latter from receiving their rewards to be: (1) The indifference of all the officials, except the medical director, to the examiner's welfare; (2) poor pay and unnecessary multiplicity of examiners. He suggested the following remedies: (1) That the medical report call for no expression as to the insurability of the risk; (2) that a confidential opinion, whenever the original report is to pass through the agent's hands, be sent directly by the examiner to the medical director; (3) that examiners be salaried, or a chief and alternate system be adopted, with a penalty for its violation, to be paid by the agent, should he employ other than the chief when available.

Dr. W. O. Bridges of Omaha believed that until the medical director had absolute authority to make and stand by an examination, regardless of the business end, there would be difficulty. He regretted that there were but few companies in this country who left the principal part of the business in the hands of the medical director. The multiplicity of examiners, he considered, was also responsible for much trouble. The only redress open to the medical examiners was to turn against those companies which would not protect them.

Dr. E. S. Clark of Sumas, Washington, thought there should be more safe risks, and until examinations were conducted with this view the trouble would not be overcome.

Dr. A. S McDaniel of San Antonio said that it had been his rule to make an honest report. While he had gained the confidence of his company his income had decreased. He found that other examiners had come in, and for some reason they got the greater number of fees.

Dr. M. A. Robison of Victor, Colorado, asked whether an examiner was justified in reporting an absolutely poor risk to a company regarding an examination made by another examiner. The case in point was that of a man who had been recommended but died within one week. Dr. Robison had been familiar with the condition before the insurance was issued and inquired whether he would have been justified in interfering with another's business.

Dr. H. G. Brainard of Los Angeles said that with most of the insurance companies the medical department was a kind of fifth wheel, which the company required but which was dominated by the business end of the concern. In his company the effort was made to have the examination papers sent direct from the examiner to the home office. He felt that the difficulty in question was one which, until the examiner was made supreme in his own field, could not be avoided. He called attention to the fact that insurance might be given to any man if a sufficient rate was charged; for instance, the man who dies next week may be insured if the rate is right. Because a man was not a first-class risk he thought it did not follow that he should be debarred.

Dr. Henry Wells Dewey of Tacoma remarked that theoretically the medical examiner was responsible to the medical department, but that practically he was much more responsible to the agent. He had in his office a scale and measuring rod which he had found kept business away from him. Agents had told him that they did not want the exact height and weight of a man who was anywhere near the limit. Another cause of difficulty, he thought, lay in the multiplicity of examiners; the agent would pick out the most lenient. With reference to interfering in the matter of a poor risk, he thought it would be a clear case of "butting in."

Dr. S. F. Sanders of Holdrege, Nebraska, spoke in protection of the medical director, who, he did not think, was entirely responsible for the appointment of the agent. He

thought benefit would result to the insurance companies if attention were paid to the matter along the lines suggested in the papers.

Dr. William T. Amos wanted it clearly understood that he was not under the second class of the heading of his paper. While he had been fairly successful, he had not made much money in the insurance business. He believed that an examiner should "butt into" the poor risks that had been accepted by other physicians.

**The Recognition of Drug Addictions in Life Insurance.**—Dr. T. D. Crothers of Hartford, Connecticut, in this paper, said that thirty per cent. or more of all alcoholics also take drugs. He divided the drug takers into two classes, the simple and complex. He gave a summary of some of the facts upon which the recognition of drug addiction must turn. He believed that a careful examination of the sight, hearing, taste, and smell would generally show the condition, notwithstanding the denials of the applicant. He believed that when the psychological studies of applicants for life insurance were made with as much minuteness as examinations of the heart, urine, and blood, the hazardous risk of drug takers as healthy, normal persons would be eliminated.

Dr. J. T. Priestley of Des Moines thought that the insurance companies suffered more from the drug takers than from any other class of people.

Dr. J. Allen Gilbert of Portland thought too little attention was given to this phase of examinations, and referred to a series of tests which he employed in examining the nervous system.

The paper was further discussed by Drs. Amos and Cardwell, and Dr. Crothers in closing said that the question of total abstinence in life insurance was fast becoming an important factor.

**President's Address.**—Dr. Denslow Lewis of Chicago, Ill., delivered this address, taking as his title "The Medical Examiner and His Work."

**Women as Risks.**—Dr. Mae H. Cardwell of Portland, Oregon, in her paper with this title, confined herself to notes and comments on the physical and moral conditions of women which make for or against their eligibility as risks in insurance. Until women have become financial independents Dr. Cardwell believed they would never be equal factors for the consideration of the companies. Statistics of the life of the female she believed should be created. The mortality in men from the effects of liquor was vastly in excess of that of women. Deaths from kidney infection through gonorrhea were as common among men as were deaths in women from the same infection of the generative apparatus. She strongly recommended that physical examination of women for insurance be extended to palpation and inspection of the pelvis, unless satisfactory evidence was given that the organs were healthy. Loyalty to the companies should prompt a warning to the applicants against habits which might develop disease, yet this warning, Dr. Cardwell thought, might be exaggerated by a nervous woman. She regarded suicide in business women a danger to be considered.

Dr. H. G. Brainard of Los Angeles thought the position of women as risks a question yet to be determined. He thought it would add much to the willingness of companies to take such risks if it were known that the pelvic organs were in good condition.

Dr. J. Allen Gilbert of Portland would insist, if it were possible, that the pelvis ought to be examined.

Dr. Amos of Portland spoke of the difficulty of finding the evidence of gonorrhea even when it was known to exist.

Dr. W. J. Means of Columbus referred to his experience in examination of women for fraternal insurance; he had found a lower mortality among women than among men.

Dr. A. Merrill Miller of Danville spoke of the difficulty of examining a woman at her home, and of the reluctance of a woman to submit to the ordeal of an examination when she realized its extent.

Dr. J. R. Wetherbee of Portland referred to the necessity for pelvic examination as brought to his attention by operations. The conditions which caused the operations would have been revealed by a pelvic examination at the time insurance was issued.

Dr. Cardwell in closing said that she believed a large majority of women would submit to pelvic examinations if the requirements were printed in the application. She did not feel that the drug habit was so important a question among women as that of suicide.

**The Relation of the Life Insurance Examiner to Local Sanitation.**—Dr. J. R. Wetherbee of Portland said that the function of a physician as a life insurance examiner should not only be to report the facts concerning a given risk, but to see that the forces in his respective locality tending to raise or lower the mortality were given his attention. He ventured the assertion that few physicians knew where the sewers of their respective cities emptied their contents. In his opinion equal responsibility rested upon the physician in the matter of educating the public in the prevention of tuberculosis. He called attention to combination policies which furnished indemnity against partial disability as well as loss of life upon the same principles as fire insurance. Should this policy become universal the responsibility of the insurance examiner for the local sanitary conditions he thought would be even greater. Dr. Wetherbee attributed the reduction of mortality from typhoid fever in Portland to the introduction of absolutely pure water from the perpetual snows of Mt. Hood. From this standpoint alone, he asserted, much money was saved to the local life insurance companies.

Dr. Denslow Lewis thought the amount of attention given by the public sanitarians not commensurate with the importance of the subject. He agreed with Dr. Wetherbee in his remarks concerning typhoid fever.

Dr. John S. Lankford of San Antonio directed attention to the importance of educating the school children in matters of health. In San Antonio the mosquito had been the subject of study by school children. They had studied the various stages of development of the mosquito and many had been killed by the children. Malaria had greatly decreased. He believed that if the children were educated in this respect when they became citizens the sanitary conditions would be properly adjusted.

Dr. Cardwell of Portland thought the hope of the people was entirely with the young, and that this work should be taken up by educational boards. The subject of ventilation as a preventive measure of disease she thought should be studied by insurance companies.

Dr. Wetherbee, in closing, said he believed that every case of typhoid fever in the city of Portland at present could be traced to outside influences. He regarded it as worthy of consideration that the mortality of typhoid fever and tuberculosis was so great with insurance companies, and that both were preventable diseases. By attention to this matter dividends could be increased, mortality decreased, and benefit accrue to all mankind.

**Suppurations in the Temporal Bone, and Their Practical Relation to Life Insurance.**—Dr. John F. Barnhill of Indianapolis presented this paper, and discussed the following phases: (1) What symptoms given by the patient and what pathological conditions found in the diseased ear should be regarded as sufficiently dangerous to reject the applicant? (2) Under what circumstances as to the condition of the discharging ear may the applicant be considered a safe risk? (3) Under what conditions as to the diseased ear should the applicant's case be postponed, and when after medicinal or surgical treatment may insurance be safely issued? The writer believed that no just decision as to whether or not any applicant was non-insurable could be made unless there were taken into consideration the symptoms obtainable from the person himself together with the absolute facts obtained from the most thorough, painstaking, and accurate examination of the condition of the middle ear and its accessory cavities. Under the second heading he

said that there were many suppurating ears which might continue indefinitely without serious risk to life. The deep cavities of the middle ear must be thoroughly inspected by an experienced aurist. To the third inquiry he replied that in the present highly developed state of otological science there were but few discharging ears that could not be cured, and the patient therefore might become an entirely safe risk in so far as the ear conditions were concerned.

The following resolutions were passed by the Association:

*Whereas,* The local medical examiner is, under present arrangements, more at the mercy of the local agent than under the protection of the medical department of the company;

*Resolved,* That the appointment of local examiners should be independent of local agents, and the number not added to to suit their desires; also

*Resolved,* That the examiners' reports should always be sent direct to the home office by the local examiner, and not through the agent; and, further,

*Resolved,* That in each city there should be one chief examiner and only such alternates as are reasonably required —one to one hundred thousand; all examinations to be made by the chief, if available, and when not, the reason to be given and his endorsement obtained before the policy be issued.

A second resolution was as follows:

*Resolved,* That the American Association of Life Insurance Surgeons, assembled in Portland, Oregon, in their regular annual session, July 10, 1905, urge that each medical college in this country provide for, and give in their regular course of instruction, a special course of instruction on life insurance examining, it being the desire of this Association to advance the knowledge of this particular side of diagnostic work, and to prepare the recent graduate for this responsibility.

The following officers were elected: *President,* Dr. Henry Wells Dewey, Tacoma, Washington; *Vice-Presidents,* Dr. A. S. McDaniel, San Antonio, Texas, Dr. M. A. Robison, Victor, Colorado, Dr. William Moore, New York City, Dr. William T. Amos, Portland; *Secretary and Treasurer,* Mr. J. G. Monihan, New York City.

Adjourned to meet at a time and place to be governed by the time and place of meeting of the American Medical Association.

## THE NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

*Stated Meeting, May 25, 1905.*

Dr. CHARLES F. ADAMS, CHAIRMAN.

**Ruptured Ectopic Gestation of the Right Horn of the Uterus.**—Dr. JOHN J. MCGRATH showed this specimen. The patient from whom it was removed was a woman of thirty, who had had four previous normal pregnancies, the last one eight months ago. She had nursed her last child up to the onset of her present illness, and her last menstruation had occurred six weeks ago. On the evening of May 13, 1905, while out doing her marketing, she was suddenly seized with a severe pain in the lower abdomen, and with great difficulty managed to get home. The symptoms pointed to a ruptured ectopic pregnancy, and the patient was transferred to the Post-Graduate Hospital, where an abdominal section was performed. The abdomen was filled to distension with free blood and some old clots. The bleeding had been so severe that the intestines were actually blanched. The case proved to be one of ectopic gestation involving the right horn of the uterus, and it was decided to amputate the horn and close the gap left in the uterus. This was done, but it was then seen that the tension on the uterine tissues was so great that it was deemed advisable to do a complete hysterectomy. After removing the uterus, a saline intravenous infusion was given, and the patient made an uninterrupted recovery. Dr. McGrath said that in dealing with a similar case in the future, he would at once resort to hysterectomy.

**A Case of True Interstitial Uterine Pregnancy.**—Dr. HIRAM N. VINEBERG showed this specimen, which he had removed from a patient operated on a year ago last summer. The woman had been pregnant about four and a half months, and was then seized with symptoms which were regarded as indicating a peritonitis. Under that diagnosis she was admitted to the Mt. Sinai Hospital, where the diagnosis of ectopic pregnancy was made by the house physician. When Dr. Vineberg saw her, the patient's temperature was 103°; pulse, 130. The abdomen was distended, and the uterus seemed to be enlarged. At the time, Dr. Vineberg said he was inclined to regard the case as one of probable ruptured uterus. Upon operation, the abdomen was found to be filled with meconium and a fetus was lying among the intestines. Upon inspection, it appeared as though the fundus of the uterus had been blown off. The placenta was still adherent to the uterus. The case proved to be one of true interstitial uterine pregnancy.

Dr. A. BROTHERS said he thought that cases of ruptured ectopic gestation of the cornu of the uterus, like the one reported by Dr. McGrath, were of very rare occurrence, and their early recognition was important on account of the danger of fatal secondary hemorrhage. In one case where he had a secondary, and in fact a tertiary hemorrhage, he had reason to believe that the pregnancy took place very close to the uterine wall. Where the uterine wall itself was involved, clamps and sutures did not accomplish what they did when the pregnancy was in the tube proper, particularly toward the fimbriated extremity, which was the easiest part to suture off. In one case of ectopic pregnancy where he had removed the uterus, the rupture took place in the lower part of the tube, and the speaker thought that suture or clamping in that region was a procedure of doubtful efficacy, and that Dr. McGrath did well in removing the uterus in his case. That was the simplest and surest way of dealing with those cases. In regard to ectopic gestation in general, the speaker called attention to the frequency with which the condition was now recognized and operated on in comparison with a decade or two ago. It often still went unrecognized, however, and was not infrequently mistaken for an ordinary abortion, and even treated as such by curettage.

Dr. VINEBERG suggested that Dr. McGrath might have completed the operation as he had at first contemplated, without removing the uterus, and he saw no reason why that should not have been done. Excision of a portion of the cornu of the uterus was frequently done in dealing with pyosalpinx, and the tissues of the uterus were sutured after cesarean section, when they were in a very softened condition.

Dr. L. J. LADINSKI said that in a case of rupture of the cornu of the uterus that came under his observation some years ago he found that it would be impossible to approximate and suture the raw surfaces without causing an undue amount of tension on the tissues. He thereupon cut out a little more of the body of the uterus, so as to make the apposition more perfect, and then closed the wound with buried sutures.

Dr. ARNOLD STURMDORF said that an attempt to limit the excision to the ruptured portion of the uterus must be based upon a clear conception of existing conditions. In the present case, the pregnancy involved the right horn of a bicornate uterus, the usual condition in so-called interstitial pregnancy. The excision of such a ruptured horn would, as in the case reported by Dr. McGrath, prove difficult and extremely bloody unless the blood supply was previously controlled, as in cesarean section, or the incision was carried down the center of the double uterus, and the involved horn ablated. In dealing with true interstitial pregnancy we had a uterine wall very much thinned out, where no amount of conservatism could restore a proper uterus, and by leaving a much deformed organ, the operator simply invited the occurrence of rupture during subsequent pregnancy. As a

general rule, such an extensive rupture of the uterine tissue should call for the total removal of the organ.

Dr. Joseph Brettauer said he did not think any rule could be laid down regarding the method of dealing with these cases. In some instances it would be well to sew up the uterus; in others to remove it. In the case reported by Dr. McGrath a hysterectomy was apparently the only thing to do. When the pregnancy involved one horn of a bicornate uterus, the problem was often a difficult one to deal with. Two such cases had come under the speaker's observation: in one he resected the uterus and in the other removed the organ completely, and since then he had reason to regret that he did not remove it in both. The after-results in the cases where the uterus was left were not very good, the scar giving rise to a great deal of trouble.

Dr. McGrath, in closing, said he still held that it was probably better surgery to amputate a uterus of the kind under discussion rather than to amputate the horn that was involved. In his case he first resorted to the latter procedure, with the idea that he could complete the operation in less time, but he found that in order to check the hemorrhage he had to draw the stitches so tightly that the tissues along the edge of the incision became blanched, and a hysterectomy was then done. In a somewhat similar case that came under his observation some years ago he removed a two months fetus and then sewed up the uterus, draining it from below. That patient made a good recovery. Still, he was inclined to believe that removal of the uterus was advisable in this class of cases, as the organ was always left in a more or less damaged condition, and was a possible menace, particularly in young women.

**The Unusual Association of Fibrous Sarcoma of the Ovary with Carcinoma of the Rectum.**—Dr. Vineberg showed this specimen, and reported the history of the case. The patient was a woman 31 years old, in whom a slight enlargement of the right ovary was first detected eighteen months ago. This proved to be a fibrosarcoma, which was removed. Subsequently she developed intestinal symptoms and one day passed a large quantity of blood at stool. Examination revealed a carcinomatous growth involving the anterior wall of the rectum. This was operated on by Dr. Vineberg about four weeks ago, and the patient made an uneventful recovery, with the exception of a fecal fistula, which he hoped to close by means of a plastic operation in case there was no further early recurrence.

**Multiple Fibroids of the Uterus, Associated with Large Fibrosarcoma of the Right Ovary.**—Dr. Vineberg showed this specimen, which was removed from a case in which the uterus was found to be filled with fibroids, while behind the lower part of the posterior vaginal wall there was a mass which proved to be a fibrosarcoma of the right ovary.

**Carcinoma of the Cervix with the Uterus Studded with Small Fibroids.**—Dr. Vineberg also showed this specimen, and said he regarded the association of these two conditions merely as a coincidence, and not, as some held, in the light of cause and effect. He did not believe that any etiological relationship existed between the uterine fibroids, degenerated or otherwise, and a malignant process of the cervix.

**Three Cases of Tubal Pregnancy.**—Reported by Dr. L. J. Ladinski. The speaker said he felt justified in reporting in detail these three cases, which had recently come under his observation, because they brought out some important factors in regard to the early diagnosis of this condition. In all three cases, the history was of no assistance in the diagnosis. In two of them a false history was purposely given, and in all three a positive diagnosis was made entirely from the physical signs. The positive diagnostic signs of early tubal pregnancy were as follows: 1. Enlarged uterus. 2. Bleeding from the uterus. The character of the bleeding was peculiar to this condition: it was a dark, grumous blood, and did not present the light color and peculiar odor of menstruation, nor the profuse bleeding, with clots and membranes, of abortion. 3. Characteristic mass on one side. The distension of a part or the whole tube caused by the gravid sac presented a fusiform, peculiarly elastic, sensitive, movable mass. There was no other pathological condition excepting hematosalpinx that would present a similar feel to the palpating finger. It could readily be differentiated from the hydrosalpinx, pyosalpinx, or an ovarian or parovarian cyst, nor was there any reason for mistaking it for a retroverted pregnant uterus, pelvic abscess, uterine tumor, etc. 4. Pain, paroxysmal in character, was always present. 5. Amenorrhea was invariably present, although the history to that effect was not always obtained. The negative signs were: 1. Absence of intrauterine pregnancy. Early intrauterine pregnancy could invariably be recognized or excluded by the presence or absence of the characteristic sign of early pregnancy on the anterior wall of the uterus. 2. Absence of rise of temperature. In tubal pregnancy, before rupture of the tube, there was never any rise of temperature, any more than there was in intrauterine pregnancy. Elevation of temperature appeared sooner or later after rupture, and indicated infection of the blood extravasated into the peritoneal cavity. In the presence of all the above signs and symptoms, Dr. Ladinski said, tubal pregnancy could be diagnosed with certainty. When one or several of the cardinal signs were absent, and in the absence of signs pointing to other lesions, a presumptive diagnosis might be made. When one or more ruptures of the tube had occurred, there were other signs and symptoms to be considered, such as sudden pain, shock, collapse, extreme anemia, rapid pulse, evidence of fluid in the peritoneal cavity, etc.

Dr. Brettauer said that while cases of tubal pregnancy were comparatively common, he wished to impress upon the members of the Section another aspect of the subject, namely, to report the cases in which a diagnosis of ectopic gestation had been made, and which afterwards proved to be something else.

Dr. Brothers, apropos of Dr. Brettauer's remarks, said he could recall two cases during the present year that he had wrongly diagnosed as ectopic gestation, and he had no doubt that others present had had a similar experience. The diagnosis could not be positively established in every instance, but even in those cases which proved to be something else, it was usually of such a nature that an operation was justifiable.

Dr. Vineberg said that in the diagnosis of tubal pregnancy there was usually a history of amenorrhea or something atypical about the menstruation. He could recall three cases, however, in which the last menstruation had been perfectly normal, and seventeen days later symptoms of ectopic gestation developed. The most common condition with which tubal pregnancy was confounded was miscarriage. Not infrequently, in these cases, the history obtained was that the woman had gone a week or two over her time, and that instrumentation had been resorted to in order to induce menstruation. The speaker raised the query whether tampering with the uterus in this way might not have been an etiological factor in the causation of the ectopic gestation, and might perhaps help explain the frequency of the condition at the present time?

Dr. Ladinski, in closing, said he regarded amenorrhea as an invariable symptom of tubal pregnancy, even though the patient did not admit it. In all three of the cases he had reported, the history was of no assistance in the diagnosis, and in two of them a false history was purposely given. Although, as some of the speakers had said, ectopic gestation was now comparatively common, it was still worthy of careful attention, and no one could make the positive diagnosis in every case. Still, it could be recognized with a fair degree of certainty. Intrauterine pregnancy could be excluded by the absence of the elastic circular area at the junction of the cervix and the anterior wall of the uterus. This he had found to be a very early and reliable sign of intrauterine pregnancy.

**A Study of the Results of Abdominal Hysterectomy for Fibroids with or without Drainage.**—Dr. Joseph Brettauer read this paper. The speaker said that prior to 1902,

after abdominal hysterectomy for fibroids, he had always drained through the vagina and sewed up the peritoneal flap, and he had had no reason to feel dissatisfied with the result of that operative procedure. About that time, the superiority of doing the operation without drainage was advocated, and this induced Dr. Brettauer to test the relative merits of the two methods. From the first of December, 1902, to the first of December, 1904, he had a series of 54 cases of abdominal hysterectomy for fibroids; in 32 of these he completed the operation with drainage, and in 22 without drainage. No difference was noted in the results of the two methods. All made an uneventful recovery; there was no difference in the effect on the pulse, temperature, or other symptoms. Since the first of December, 1904, he had operated on eighteen additional cases without drainage, and the results were equally satisfactory.

Dr. Vineberg said the results obtained by Dr. Brettauer showed that what we often regarded as essential steps in the technique of an operation were after all unimportant. More depended upon the operator himself than upon the technique that he employed. Personally, Dr. Vineberg said, he sewed up the cervix and peritoneum in every case, excepting where the cervix was lacerated and hypertrophied or otherwise diseased; that he considered it a good plan to remove it, either *en masse* with the tumor or subsequently by itself.

Dr. A. H. Goelet said he thought the idea that drainage was necessary in these cases arose from the fact that silk was formerly regarded as the best suture material in the ligation of the uterine arteries. Since catgut had been substituted for silk, and could be used with perfect safety, he saw no necessity for draining the uterine cavity in this class of operations.

Dr. Brothers said the two series of cases reported by Dr. Brettauer scarcely offered a fair basis of comparison, as in both he sewed up the peritoneal flap. If the peritoneal cavity had been left open and drained, the comparison would have been more interesting.

Dr. Ladinski said it was his custom to sew up the peritoneum and do away with drainage, and his results had been entirely satisfactory. For some years past, he had favored the abdominal route, both for operation and drainage, and he avoided, as far as possible, putting dressings through the vagina after he had opened the abdominal cavity.

---

**The Blood Changes Following Typhoid Inoculation.**—W. B. Leishman reports the results obtained in estimating the blood changes in eighty-six members of a regiment vaccinated with typhoid serum as a prophylactic against the disease. The inoculations were carried on for about one month. The vaccine was made from a strain isolated from the spleen, and about five years old, being of low virulence. The culture flasks were incubated for forty-two hours, tested, mixed, and sterilized. They were then standardized by counting the bacilli. The author and his assistants tested the dose on themselves, and found 0.1 cubic centimeter sufficient. The men were divided into groups of five to eight men. Their blood was tested to ascertain what changes had taken place in it. Even very small doses of vaccine caused a remarkable development of protective substances in the blood. Four weeks after the first inoculations the amount of these substances remained considerably above normal. In no case did the reaction appear excessive. At the end of forty-eight hours all symptoms had disappeared, except in a few cases, in which there was pain and tenderness at the site of inoculation. The reaction was proportionate to the dosage. The largest doses produced the largest amount of protective substances. There was no evidence of a negative phase on first or on reinoculations. The interval between the first and second inoculations was eleven days. At this time the protective substances are rapidly increasing, and reinoculation stimulates rather than retards their further development.—*Journal of the Royal Army Medical Corps.*

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 23, 1905:

| | Cases | Deaths |
|---|---|---|
| Measles | 69 | 1 |
| Diphtheria and Croup | 155 | 18 |
| Scarlet Fever | 62 | 1 |
| Smallpox | .... | ..... |
| Chickenpox | 20 | ..... |
| Tuberculosis | 350 | 142 |
| Typhoid Fever | 124 | 15 |
| Cerebrospinal Meningitis | 11 | 15 |
| Typhus Fever | ..... | ..... |
| Yellow Fever | ..... | ..... |
| Cholera | ..... | ..... |
| Totals | 791 | 192 |

**Acid Autointoxication in Infancy and Childhood.**—John Lovett Morse tells us that the urine of healthy sucklings does not contain acetone, or it is in only very small quantities. In abnormal conditions, when it does appear, it is mainly excreted by the lungs, and not by the urine as in adults. The organism of the child reacts to the acidosis by an increase in the excretion of ammonia. The author has tested a series of 150 cases, and believes that acid bodies are present in the urine of infants and children under about the same conditions as in adults. They are often present in acute diseases with high fever, and disappear with the fall of temperature. Certain disturbances of digestion associated with the presence of acetone have peculiar symptoms, which are probably due to acid intoxication, which is not primary but secondary. In some cases of recurrent vomiting with acid intoxication the symptoms are due to the acid. In spite of the fact that the amount of acid is much smaller than that found in diabetes, its presence is of importance in making the diagnosis and in the treatment. Acetone bodies are never found when the diet is of milk alone; on pure meat diet they appear, and disappear on the substitution of a carbohydrate diet. The symptoms of aciduria are concerned with the nervous system—excitability and insomnia; or gastrointestinal, vomiting and constipation. The odor of acetone is in the breath, preceding the vomiting by twenty-four to forty-eight hours.—*Archives of Pediatrics.*

**Maternal Diet with the Object of Lessening the Bony Development of the Fetus.**—William Gillespie discusses the question of whether, in case we were able to find a diet which would limit the formation of bone in the infant skull, it would be of any advantage to the mother at the time of labor. Since we do not always find ill-developed children when the mother has had excessive vomiting, he concludes that the nutrition of the fetus is not affected by that of the mother in respect to the ossification of the bones. Should we interfere and obtain less development the fetus might not go to term, and might then be too undeveloped to live. Unless the mother has a deformed pelvis we cannot be sure that all her labors will be abnormal because the first one has been so. A child whose head is soft and undeveloped is found practically to present an obstacle to quick delivery, because the uterine force cannot be exerted to advantage in pressing on this soft body. A harder head, and a less yielding spine are found to assist the exercise of the uterine contractions. The slowest labors are those that come on prematurely. In the case of a large, vigorous child, the transmission of the force is more perfect. There is also a lessened amount of reflex stimulus to contraction furnished by a soft head. The author concludes that a lessened amount of lime in the bones would be a clear disadvantage to the mother in labor.—*The Lancet-Clinic.*

### THE CHOICE OF METHOD IN OPERATING UPON THE HYPERTROPHIED PROSTATE.*

By WILLY MEYER, M.D.,

NEW YORK.

PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO THE GERMAN HOSPITAL; CONSULTING SURGEON TO THE NEW YORK SKIN AND CANCER HOSPITAL AND TO THE NEW YORK INFIRMARY.

Before I proceed to the subject of my paper, I wish to express my sincere thanks for the invitation extended to me and to assure you that I keenly appreciate the privilege of appearing before your society, many of whose members I have met before or know well from their writings, and of whose distinguished president I have long been an ardent admirer.

As you will have seen from the program, the subject I shall speak on to-night is "The Choice of Method in Operating Upon the Hypertrophied Prostate." The main purpose of my remarks is to emphasize the desirability of the surgeon's practising each of the three standard operative measures recognized to-day in the operative treatment of prostatic enlargement. There are many surgeons who make use of but one method to the absolute exclusion of the two others. Often, at medical meetings, we hear them declare the one method of their choice to be the only one worthy of consideration and adoption. Such a position I believe to be decidedly wrong. If we find it incumbent upon us to individualize in so many other surgical diseases, I see no reason why we should not do likewise when operating upon prostatics—who are in addition usually afflicted with the infirmities of old age. Why should we withhold from these patients any of the benefits that may be bestowed by exploiting to the full all the possibilities afforded by advanced prostatic surgery? There can be no question but that each of the three operations, *i.e.* perineal and suprapubic prostatectomy and galvano-caustic prostatotomy (Bottini's operation) has its decided merits and will hold its own distinct place in the surgery of the prostate.

A discussion of the choice of *method* of operation for prostatic enlargement, although principally of surgical interest, also concerns the general practitioner. Of course, the question that is of primary importance to him is, *When* shall operation be recommended? In a previous paper (Medical Record, June 25, 1904) I stated that a well-to-do patient who is perfectly able to observe all necessary aseptic precautions may be allowed to practise self-catheterization, if he be opposed to operation. However, when it comes to the rank and file of prostatics, the men who have to toil for a living for themselves and family, surgical intervention should, by all means, be urgently advised as soon as the time has arrived when the catheter must be given *into the hands of the patient himself for regular use.*

And surely, in view of the present status of prostatic surgery, I think we are not only justified, but in honor bound, to give such advice; for the death-rate following operative procedure in trained hands is 5 per cent. and less; whereas the mortality due to pyelonephritis resulting from self-catheterization in this class of patients would surely prove to be much greater could reliable statistics be compiled.

Personally, I have tried to obtain due experience with every one of the operative procedures now recognized, and, as a result of such experience, I now practise not one, but all three methods, making my selection in accordance with the conditions found in the individual case.

I started with Bottini's operation, and, partially encouraged by the results obtained, partially goaded on by the unwarranted opposition the operation met with on this side of the Atlantic, I extended this period over five years, from October, 1897, to October, 1902, operating in all upon fifty-nine cases. They are not considered in this article. (See Medical Record, October 24, 1903.)

During this time I satisfied myself that by means of galvano-caustic prostatotomy not only relief of the condition under consideration, but a cure may be effected, and this sometimes in cases in which neither of the more radical operations could possibly have been done to advantage. I thus came to the unassailable conclusion that Bottini's operation cannot in justice be denied a place among the operations at our disposal for the relief of prostatic hypertrophy.

From October, 1902, up to the present time, I have performed perineal prostatectomy nine times, (once prior to this time for a suppurating enlarged gland), the suprapubic operation twenty-two times, and Bottini's operation seven times.

Among the nine patients treated by the perineal route, one, a man of seventy-eight years, with far-advanced paralysis agitans, had suppuration of the gland. He was septic at the time of operation, and only his intense suffering and total infirmity induced me to operate. However, the enucleation, though successfully performed at his home, did not save him; he was beyond surgical help, and died under septic symptoms sixty hours later. Another patient died on the table, with the operation almost completed, of general anesthesia, administered by a young, inexperienced narcotizer.

Deducting these two deaths, which surely cannot be attributed to the operation as such, my mortality in perineal prostatectomy so far is *nil.*

Of the seven patients that survived operation, I would here relate the history of but one, a gentleman, fifty-seven years of age, who had a stone crushed by one of our New York surgeons in 1899. In June, 1900, I performed a litholapaxy for recurrent vesical calculus. The cystoscope showed two stones and a somewhat enlarged prostate. Visual inspection eight days, and again seven months after crushing showed the bladder entirely free from débris. One and a half years later five small calculi

* Read, by invitation, before the Chicago Medical Society, May 24, 1905.

were seen in the bladder, and removd by litholapaxy. In the summer of the same year he again felt annoyed by the same symptoms. With good illumination, I counted nineteen small vesical calculi, the largest being of about the size of a big pea. Questioned by the patient how I explained such continued recurrence, I could but say that the gravel discharged by the kidneys could not pass out of the bladder on account of the obstruction caused by the prostate, and that it would probably be advisable to have cystoscopy performed at regular intervals, adding evacuation whenever necessary. This prediction proved to be correct. Three times later, at intervals varying from six to eight months, the patient had to submit to cystoscopy and evacuation by suction. Although I, personally, was opposed to prostatectomy on account of the very slight palpable and visible enlargement, the patient by this time insisted upon it. Thus, in January, 1904, I did the perenial operation, which proved rather difficult technically on account of the glands not representing a tumor of certain size that could be attacked, but being made up of many small round tumors of a pea's to a hazelnut's size. The ejaculatory bridge was carefully preserved. Many small calculi were washed out of the bladder. Rapid recovery followed, the patient leaving the hospital just two weeks after operation. Since then he has had no further trouble. At the time of the last examination, six weeks ago, there was not a drop of residual urine, and the cystoscope showed no trace of calculi in the bladder.

The foregoing represents a typical case of early operation dictated by the wish of the patient on account of unbearable subjective annoyance. From an operative standpoint, it proved to be a difficult task, confirming the experience so often made in these cases, that the smaller the prostate the more difficult the operation and *vice versa*.

Of the twenty-two patients upon whom I did suprapubic prostatectomy, three were affected with cancer of the gland. Two of these latter made a good recovery from the operation, but died soon after, one of embolic pneumonia, in the fourth week after operation; the other, who had multiple pre- and retrovesical cancerous glands, of pyelonephritis, nine weeks after operation. The third case afflicted with cancer was that of a decrepit man, seventy-six years of age, on whom I had operated merely to relieve his intense suffering. He survived the immediate effects of the operation, but died suddenly on the second day. Of the remaining nineteen patients suffering from benign prostatic enlargement, seventeen recovered, and are living to-day, with their bladder function fully restored; two died, but in neither of these can death be attributed to the operation as such. One, a man sixty-three years of age, with total retention of recent date, who had to be catheterized at regular intervals, developed urethral fever the day after his bladder had been emptied by a night orderly. Continued intraurethral and intravesical instrumentation being required, the temperature, of course, did not go down. With the patient in this condition, I performed prostatectomy, emboldened by the successful issue of the same operation under similar conditions in a man eighty years old, done a few days before. But this time the procedure proved to be an unwise step. I should have merely opened the bladder, providing for thorough drainage, and removed the gland at a second sitting, after the temperature had become normal. As it was, the patient reached his bed with a temperature of 104°, which rose to 105° the next day, and continued high, accompanied by suppression of urine, until death, forty-eight hours later. Post morten was refused. In the absence of clinical manifestations of lung complication, death in this case, evidently, was due to acute septic pyelonephritis.

The lesson I have drawn from this sad experience is never to enucleate the gland in the presence of fever and suppression of urine (urethral fever), but to be satisfied with establishing drainage, removing the prostate through the same opening after conditions have become normal again.

The second patient was a much reduced man of seventy-four, with an immense gland and marked arteriosclerosis. He had been a sufferer for some ten years. Total enucleation, not intracapsular enucleation, was carried out, as the right point of cleavage could not be made out. The capsula propria was found to be fully three-quarters of an inch thick, a great mass of glandular tissue being firmly adherent to its inner surface. The patient was out of bed on the third day after the operation, with good drainage and normal temperature. On the eighth day after the operation, without any apparent reason, he suddenly began to refuse nourishment. In spite of very careful nursing he succumbed on the eighteenth day after operation. No autopsy.

In view of the great emaciation of the patient, Bottini's operation in this case perhaps would have been the safer procedure. It was the large size of the prostate that prompted me to do the extirpation. In this case again, the still existing defect in our therapeutic resources in regard to proper nourishment by hypodermic injection, was brought home to me. As matters were, we could only resort to nutrient enemata and hypodermoclyses, which were given twice every twenty-four hours for ten days. Food, poured into the stomach through a tube, was regularly rejected.

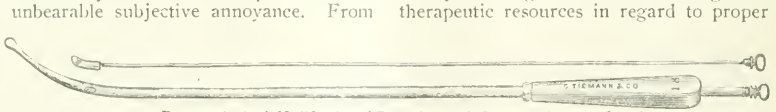

Fig. 1.—Author's Modification of Trendelenburg's Prostatic Catheter Sound.

In two of the patients in whom the perineal operation was done, and in three in whom the suprapubic route was chosen, the trouble was complicated with vesical stone.

Among the seventeen cases that recovered after the suprapubic operation, and are living to-day, there are two of sufficient interest, I think, to warrant me in briefly relating their histories.

Case XIII.—At midnight, on February 13, this year, I was hurriedly called in consultation on a case of total retention in a man eighty years of age. I found a well-preserved man who had had prostatic trouble since about a year; frequent catheterization, done by the family physician, had become necessary. For several hours prior to my arrival attempts had been made to enter the patient's bladder, but without avail; severe hemorrhage had set in. Now the bladder reached above the umbilicus; the agony was intense. As in so many instances before, Trendelenburg's prostatic catheter sound* here, too, passed with ease, but the intravesical hemorrhage continued. Twelve hours later the patient had a chill; his general condition rapidly became very poor. Immediate operation at the hospital suggested and consented to by the family on one condition, namely,

*I would again call attention to this beautiful instrument as I had it modified fourteen years ago; its merits do not seem to be sufficiently recognized by the profession generally. I described it in the *New York Medical Journal*, August 6, 1902, recommending its use. (See Fig. 1.)

that the prostate be removed at the same sitting. Against my better judgment I agreed, for the patient's condition demanded relief. Superficial general anesthesia. Bladder distended to its utmost capacity, filled with an immense amount of old blood clots and a small amount of foul urine. Time consumed in enucleating gland, five minutes. Entire bladder wound left open; drainage as usual. A few interrupted layer sutures of muscle, fascia, and skin in the upper part of the wound. Sixteen hours later, intermittent heart, edema of lungs; patient unconscious. He was at once taken out of bed and placed in an easy chair, kept awake by continual conversation and hypodermic as well as internal stimulation. He was kept in a sitting posture day and night. Slow but steady improvement was apparent. In the course of the fourth night after the operation the patient was allowed a nap of two hours in bed. With very careful nursing, I had the satisfaction of seeing the old gentleman recover entirely. To-day he is in perfect health.

This case teaches the possibility of successfully removing the prostate with the patient in such a precarious condition, but it also shows the dangers of such a procedure. It certainly seems best to delay extirpating the gland until the patient has recovered from the operation of establishing the absolutely imperative drainage. More lives will thus be saved and our statistics improved.

This case further shows the great value of the erect posture as an aid in our efforts to overcome the threatening lung complications. I am convinced that, had I allowed the patient to remain in the horizontal posture for another hour or two, there would have been no chance of pulling him through.

I hope not to become tiresome if I add right here the history of another patient whose condition has been of great interest to me for the last seven years.

Case XVII.—Mr. S., very anemic, fifty-four years of age, was sent to me for Bottini's operation in the fall of 1898. The cystoscope showed the presence of a large median lobe. I did the operation on November 11. Five weeks later, he had not a drop of residuum. Gradually his urine became absolutely clear. One year after the operation I considered the result obtained in this case the best I had had up to that time, but slowly increasing difficulty in urination and a corresponding residuum reappeared. This was hard to understand in view of the excellent original result. The cystoscope explained the cause. I saw clearly that I had divided the median lobe in two, the two halves now acting as valves blocking the outflow whenever the detrusor contracted. I now advised prostatectomy. But both he and his wife, who, besides, was seriously ill at the time, were opposed to the cutting operation. I therefore agreed to do a second Bottini, hoping that by still further lowering the point of exit in relation to the trigonum, some improvement might be brought. This hope was not realized. The second galvano-caustic operation (December 13, 1900) did not bring material benefit. I then lost sight of the patient. Four weeks ago he reappeared at my office. I learned that his wife had been successfully operated upon last summer and that he was now ready for more radical work. He had been using the catheter with vesical irrigation for the last year and a half. The cystoscope showed the same condition as four and one-half years ago, but somewhat more pronounced. I could clearly see the three grooves that had been cut, lying in the half shade, and had to conclude that in spite of my having successfully lowered the originally greatly raised internal urethral orifice by the second Bottini down to the basfond, the two parts of the divided soft gland became tightly shut on contraction of the detrusor, acting just like the two halves of a double swinging door. Suprapubic incision, done on April 22, 1905, fully corroborated the cystoscopic diagnosis: the entire prostate with its median lobe had been divided perpendicularly. Evidently the intravesical tumor had been somewhat irregular in shape, since the greater half of the prostate lay on the right side, although it had been divided exactly in the median line. The subsequent enucleation was, of course, more difficult than usual, but could be well done in spite of the double Bottini, although there was more hemorrhage than seen in the average case. It was shown by the continuation of the hemorrhage, after the patient had been returned to his bed, that the small arteries of the capsule had lost their elasticity on account of the former cauterization. Four hours later the pulse was very weak in spite of hypodermoclysis and an intravenous saline infusion. I had to reopen the bladder under general anesthesia, clear out the blood clots, and tie off a projecting portion of the capsule, from the tip of which, drop after drop, the arterial blood trickled down, representing a typical parenchymatous hemorrhage. Now a Mercier's catheter was tied in the urethra and the bed of the prostate firmly packed around the same. The bladder was also filled with gauze and left wide open. Muscle, fascia, and skin were closed with layer sutures in the upper half of the wound. The patient made an uninterrupted recovery. On the fifth day after the operation he was out of bed. To-day his wound is almost healed and the bladder function fully restored. This case nicely illustrates:

1. How deep and wide it is possible to cut the grooves with the galvano-caustic knife; for at the time of doing the prostatectomy, I could with ease pass my finger through the median furrow down to the base of the bladder;

2. That a median lobe should represent rather a contraindication to Bottini's operation, if the patient's general condition is such as to warrant the more serious operation of total enucleation. I say this on the basis of this one, but important experience, and although in my series of sixty-six cases of Bottini's operation, I have a number in which, despite the presence of a median lobe, the bladder function has been restored to such a degree as to justify me in calling them cured;

3. The value of the cystoscope in explaining the mechanical conditions at the vesical neck;

4. That Bottini's operation, even though done twice, does not preclude the successful performance of prostatectomy at a later date;

5. Not to rely in such cases upon the spontaneous ceasing of the hemorrhage, as usually seen, but to promptly stop bleeding at the time of the operation.

The seven patients in whom I did galvano-caustic prostatectomy, since October, 1902, all recovered. They were thus operated upon, as prostatectomy was refused or did not seem justifiable,—my rule now being to always do the more radical operation, unless there be contraindications, such as far-advanced diabetes, serious heart lesions, evidence of malignant disease that has transgressed the prostatic capsule, etc.

One of them, sixty-four years of age, had advanced diabetes, was very weak, and did not appear to me to be a fit subject for major surgical intervention. I therefore cut three grooves through the obstructing gland, and had the satisfaction of seeing the patient fully recover. At a recent examination he still had two ounces of residual urine, but considers himself entirely cured, not being obliged to ever use the catheter.

The second patient was a man seventy years of age, with a very large obstructing gland. This case, from a surgical standpoint, seemed to me to be the

best suited for prostatectomy. However, the man had such serious and alarming attacks of angina pectoris, that on one occasion he almost succumbed to ordinary catheterization which had to be regularly performed for his total retention. He suddenly developed edema of the lungs, and almost died under our hands. Bottini's operation was therefore resorted to, under local anesthesia, followed by a most careful after-treatment. At the end of four weeks he had regained voluntary micturition, and was discharged with a residual urine of not quite one ounce. At the present time his urinary functions are in excellent condition, although he has since had another most severe attack of cardiospasm.

Advanced chronic valvular disease of the heart was found a contraindication to the cutting operation in a third patient; general debility with great emaciation, in a fourth. In the latter Bottini's operation was advised and done as a preliminary step to prostatectomy. However, the improvement after the galvano-caustic division was so great, that later he refused all further surgical intervention. In two other patients the family was unalterably opposed to the use of the knife. Bottini's operation rescued both from catheter life, the only alternative remaining. In the seventh case, a man seventy-six years old, rectal palpation showed the prostate hard, nodular and ill defined. The suspicion of malignant degeneration was strengthened by the cystoscopic examination. Bottini's operation seemed to me indicated rather than the cutting operation, and has brought decided improvement so far. Should future developments prove the suspicion of cancer to have been unfounded and the patient be dissatisfied with his condition, prostatectomy can still be added.

Bottini's operation, being a purely intravesical intervention in which the gland causing the obstruction is not removed, but merely furrowed, has, of necessity, a larger percentage of failures, while the death-rate is about the same as that of the operation with the knife. In addition to this, Bottini's operation sometimes entails a difficult and tedious after-treatment, greatly taxing the skill, time, and patience of the attending surgeon. This is also one of the reasons why I now invariably advise ward patients to submit to prostatectomy rather than to Bottini's operation, as long as the patient's condition seems to warrant extirpation.

But, in spite of all this, we should not lose sight of the fact, which my personal experience and observation now extending over a period of almost eight years, have confirmed, namely, that galvano-caustic prostatectomy, too, can, even in difficult cases, improve or cure the trouble in question. Surgeons, therefore, have no right, it seems to me, to at once relegate to the catheter patients who refuse the operation with the knife, or in whom the same is contraindicated. Nay, they are in duty bound to give such patients the benefit of Bottini's operation. Only if any kind of operative intervention is refused should the catheter be suggested.

Reviewing my consecutive work in prostatic surgery from October, 1902, until March, 1905, and excluding the two fatal cases treated by means of perineal prostatectomy, in which death could not be attributed to the operation, as such, as also the three with cancer of the prostate, operated upon by the suprapubic route, it appears that in a series of twenty-six operations (seven perineal and thirteen suprapubic prostatectomies and six galvano-caustic prostatotomies) for benign prostatic obstruction, done within twenty-nine months, there was no death. Since that time, as stated above, I have done six further suprapubic enucleations with two deaths. This experience shows the truth of Pilcher's words (*Annals of Surgery*, April, 1905, p. 565): "There must of necessity be some mortality in any and every kind of surgical intervention in prostatic patients. Sepsis, urinary insufficiency and the multiple degenerations incident to old age are complications in varying degrees of combination, that have to be reckoned with in many instances and which must determine a fatal exit unavoidably in a certain proportion." And later, "At present it would seem that the surgeon must expect a death-rate for prostatectomy of from 5 to 10 per cent. While he may in some instances possibly have the good fortune to have a considerable series of cases without a death, yet a longer continuation of work has been found, even in the experience of the most careful and fortunate, to be attended with a share of mortality."

With reference to the functional results and sequelæ in my cases of prostatectomy, I would state that every one of the twenty-four patients whose gland was enucleated, regained full power of urination. Persistent dribbling or incontinence was not observed. One man of sixty-four developed a small rectourethral fistula on the eleventh day after removal of the gland by way of the perineum. A large mass of fecal matter, too large evidently to be passed per anum, in spite of purgatives and enemata given before and after the operation, had produced pressure necrosis in a very small place. It had to be removed piecemeal with the fingers. To-day, two and one-half years after operation, the fistula is still present without causing any appreciable annoyance. Now and then during micturition some urine runs into the rectum. The sphincter ani muscles have been trained, however, to retain the urine in the rectum, which is not irritated. The patient always sits down for urination. My proposition to close the communication by operation has been refused.

Such a rectourethral fistula would, of course, never occur after the suprapubic operation, a point in favor of the latter. Nor have I personally ever seen a suprapubic vesical fistula.

Epididymitis and an obstinate perineal fistula occurred in one patient, whose gland harbored an abscess at the time of operation. Epididymitis without abscess formation was noticed in four other cases—two perineal and two suprapubic prostatectomies—at various times after the operation, and without the catheter having been passed for vesical irrigation or the sound for stretching the urethra. None of the patients in whom I did suprapubic prostatectomy developed ventral hernia, as others claim to have seen it after this operation. This, I think, is ascribable to the fact that I carefully suture each layer of the median incision, muscle, fascia, and skin, separately, down to the lower corner of the wound through which the drainage tube and tampons emerge.

Examination of the specimens obtained has convinced me that the prostatic urethra cannot possibly be preserved intact in every case. Even by exercising the greatest care and gentleness it is sometimes unavoidable to remove one-sixth to one-fourth inch of the urethral mucosa immediately attached to the internal urethral orifice. In fact, I consider it a technical impossibility in some cases to prevent this, especially in those with the fibrous variety of gland, in which the urethra is closely surrounded by the tissues of the hypertrophied prostate. In the cases with considerable lengthening of the canal (up to 25-27 cm.) I often consider the loss of some of this superfluous length an advantage, in that the urethra is more likely to maintain a straight course when not quite so long. At any rate I have found no

difference as regards final results in the patients in whom a small portion of the vesical end of the urethral canal was removed, and those in which it was preserved entire.

As to whether we attack the prostate by way of the perineum or by the suprapubic route is, I think, of little consequence. It may be said to be a matter of personal inclination more than anything else, at least up to the present time. Surely, both methods are highly commendable, for both yield equally good and satisfactory results.

The objection raised by many that in suprapubic prostatectomy one has to rely entirely upon the sense of touch, while perineal enucleation, especially if done with the help of tractors, can be carried out under direct visual inspection, is not supported by the facts. The loosening of the prostate from the base of the bladder—surely the most important part of the perineal operation, especially in the presence of a median lobe—must always be done by the sense of touch.

A condition which makes the suprapubic operation somewhat more disagreeable to the patient is the continuous leakage above the pubes during the first one and one-half to three weeks, so long as permanent suction drainage is not provided for. Perhaps this slight disadvantage will be overcome in the course of time. If, for instance, in favorable cases we were to abstain from packing the bed of the gland with gauze, and invert the anterior vesical wall around the drainage-tube (Kader-Gibson method), the hole left in the bladder after the removal of the tube would cause little or no leakage, and would heal up quickly. For cases in which gauze packing is imperative, we should have to search for other methods. Perhaps secondary closure of the wound with chromicized catgut, the sutures being placed at the time of the operation, might here prove of value.

In cases of perineal prostatectomy, the chances are that the patient will regain control of the muscle very soon after the removal of the tube, provided material injury to the internal sphincter muscle has been avoided, possibly by the enucleation resection (preservation of the ejaculatory bridge). He then would discharge his urine on call, through the urethra and perineal wound, with rapid decrease of discharge through the latter route, surely a more comfortable condition than suprapubic leakage.

In patients with but moderate or no vesical infection, one might leave the membranous urethra intact and enucleate the gland, according to the usual custom, through a longitudinal incision of the capsule on either side. The patient could then urinate normally, or the bladder could be drained through a catheter introduced through the entire length of the canal. Of course, in proceeding in this way, we should have to forego the advantage of using a tractor in pulling down the gland. But if the operation were successfully carried out without injury to the prostatic urethra and vesical mucosa, normal conditions would be speedily restored in an almost ideal way.

As to the technique I employ in prostatectomy, I would say that in perineal enucleation it is the same as that generally practised. I have worked with and without tractors. They certainly simplify the work, but are not, it seems to me, essential.

In the suprapubic operation my procedure differs from the one I find usually described. After thorough irrigation, with warm 1 per cent. boric lotion, 8 to 10 ounces are filled into the bladder, the catheter is plugged and held within the urethra by means of a roller bandage, which is sufficiently tightly wound around the penis to prevent leakage alongside the catheter. The vesical end of the latter is made to enter the bladder for at least one inch. It represents a convenient landmark during the shelling-out of the gland, and is removed with the bandage right after enucleation has been accomplished. I open the bladder by a liberal cut, about two to two and one-half inches long, with the patient in Trendelenburg's posture of about 30°, view the vesical mucosa and the prostate, comparing its actual condition with the cystoscopic appearance, the borders of the wound being held apart by blunt retractors, and incise the prostatic capsule close to the internal urethral orifice, under the guidance of my eyes. Then enucleation of the gland is proceeded with. The resulting hemorrhage, of course, forbids further inspection. In difficult cases and stout patients all five fingers of the hand dip below the level of the abdominal wound and enter the bladder. The wound in the latter can be easily stretched. I have found it of advantage to change hands during the work, *i.e.* to commence enucleation with the left fore- and middle finger and then use the right hand in pronounced pronation to finish the task. In this way, it will be seen that the "good deal of physical strength" that some surgeons claim to be required to carry out this operation are not essential. Any man can do the operation, even if he has little strength. The smaller the hand, the easier it can dip into the bladder, and the operation can be done without the aid of an assistant to press the gland up from the rectum, a help which I have not needed in a single case. It simplifies the procedure if the surgeon alone attends to the enucleation.

In view of these advantages, I consider this changing of hands of importance. I am sure it will help to make friends for the suprapubic enucleation.

The tampon of aseptic gauze is placed under the guidance of the eye with the patient in high Trendelenburg posture, after the bed of the gland has been dried by sponging, and pressed firmly in place for a few moments. The cut borders of the gauze tampon I have of late folded inward and provided with a seam on three sides to prevent threads of gauze from coming loose and acting as foreign bodies in the bladder. Then the bladder wound is sutured below the tampon with chromacized catgut. Formerly I used interrupted sutures for this purpose, but have recently tried a continuous suture, which facilitates this part of the work. Of course care has to be taken not to include the mucous membrane in the grasp. The needleholder known as "Küster's Swan" I have found very handy for placing the deep sutures. Now the table is lowered again.

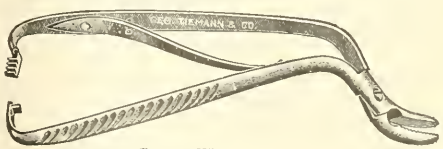

Fig. 2.—Küster's Swan.*

Before closing the upper angle of the vesical incision with a few interrupted stitches of chromicized catgut, a drainage tube, the size of a pencil with an additional hole near its tip, is pushed down to the base of the bladder right above the tampon. It is fastened to the vesical wall with a stitch of ordinary fine catgut. The prevesical and properitoneal space also each receive an aseptic gauze tampon. Tube and tampons emerge at the lower angle of the wound, which is kept open, the other two-thirds

* The illustration represents a modification of Küster's original design, which, I hope, will be found useful also by others.

having been closed layer by layer, chromicized catgut being used for muscle and fascia, and silkworm gut for the skin. Before dressings are applied, the drainage tube is again anchored to the skin by a loose stitch of silkworm gut. With this treatment the healing of the bladder wound does not take longer than if a smaller incision had been made. It always closes promptly. The wound in the abdominal wall also invariably heals by first intention.

Regarding the time consumed by the operation, it may be said in a general way that the suprapubic enucleation can usually be accomplished in less time than the perineal extirpation. I have repeatedly succeeded in completing the operation as such in four minutes, *i.e.* counting from the time of making the skin incision to the moment that the gland is delivered from its bed. More than six minutes are rarely needed. This point is, of course, of real importance only in the very aged. The average time used till the completion of the dressing is from fifteen to twenty minutes.

With reference to anesthesia, it may be worth mentioning that all but one of my prostatectomies were done under general anesthesia, with a mixture of chloroform, ether and ethyl chloride (anæsthol), preceded by a hypodermic of morphine (¼ grain). The one exception was operated upon under spinal anesthesia. All stood the narcosis very nicely. Of course, the time of anesthesia was made as brief as possible, by preparing the patient on the operating table before beginning the administration of the anesthetic, and allowing him to come out of the narcosis, to some extent or entirely, with the completion of the enucleation.

Regarding the after-treatment, I might mention that for the first two days patients are kept in the lateroabdominal posture, alternately on the right and left side, securing thorough vesical drainage by gravitation, the tube being connected with a bottle under the bed. Frequent breathing exercises are insisted upon. Urotropine, usually with salol, is given internally. The tampons are removed after forty-eight hours, the tube, according to convenience, on the fifth to seventh day after the operation. The patients are usually out of bed on the second or third day, older men on the morning following the operation. Before removing the tube the bladder is thoroughly flushed through the tube with a 1 per cent. boric acid solution followed by a solution of ichthargan 1:5000. After this the bladder is left alone and the wound dressed with balsam Peru gauze and a pad of gauze with borated vaseline, until cicatrization is completed. Gauze cotton pads placed on top of this dressing, and changed frequently, absorb the leakage above the pubes. The patients usually commence to urinate through the normal channel in the course of the third week after operation; some begin as early as the seventh, ninth, or twelfth day to pass almost the entire twenty-four hours' urine through the normal passage. Of course, the suprapubic wound then dries up quickly. The average time of hospital treatment is three weeks. Some of my patients left earlier and were treated by the family physician, or came to the office to have the dressings renewed. Some stayed longer. The wound usually becomes closed some time between the twenty-sixth and thirtieth day after operation. Sounding I consider superfluous during this time, although it may become necessary later in case of a sinus or stricture. I had this experience in one case only, and that in an early operation on a fibrous prostate, in a patient from the West Indies, who feared not to have the proper treatment at home in the event of sudden retention. Part of the gland was firmly adherent to its capsule, and this, in turn, to one spermatic vesicle. The latter was pulled up into the abdominal wound together with the tumor, gently stripped off and replaced after a small rent in its wall had been stitched up with catgut. I think it would have been wiser had I extirpated the respective vesicle, as I imagine the organ did not slip back into its normal place, but partially blocks the urethral canal.

As to cystoscopy, I believe that in patients with a prostate palpable per rectum and in whom the suprapubic operation is to be done, this examination may be dispensed with, although a more definite knowledge of intravesical conditions will often be found an advantage.

In patients in whom the perineal route of operation has been decided upon, cystoscopy is indicated in order to determine the presence or absence of a median lobe and of calculi.

In the cases that are to be operated upon by Bottini's method, cystoscopy should never be omitted.

Cystoscopy is, furthermore, absolutely essential in that 33 per cent. of prostatics, who present all the clinical symptoms of prostatic enlargement, but in whom no tumor can be palpated per rectum, the growth being entirely intravesical or entirely missing (prostatism).

The fact that I found three sure cases and one highly suspicious of prostatic cancer among the thirty-eight patients operated upon within the last two and one-half years, has made me meditate upon the subject. Perhaps this trouble is much more common than is generally believed. Such a possibility might almost induce one to question the advisability of practising Rydygier's enucleation-resection (Young's preservation of the ejaculatory bridge), especially if it were shown that equally good functional results can be obtained by removing the entire gland through the suprapubic incision, and even better results, as present experience seems to indicate, in regard to the preservation of sexual power. The advisability of accepting as a routine measure the retention of a portion of the gland as a protection against possible injury to the ejaculatory ducts might certainly be doubted in view of the abovementioned possibilities.

It is true our experience so far does not furnish sufficient cause for such an apprehension; yet enucleation resection is an operation of very recent date, and it certainly must be conceded that it is not an altogether theoretical objection to say that, in view of the possible presence of a beginning prostatic cancer at the time of operation, total removal of the gland is preferable to partial extirpation, especially if the results of the former are equal or even superior to those of the latter.

In the more advanced cases of carcinoma, I personally believe Bottini's operation to be preferable to enucleation. For, in these cases the prevesical and retroperitoneal glands are nearly always more or less extensively involved, so that it hardly seems worth while to subject the patient to the more serious operation and run the risk of adding to the already existing misery, without the possibility of effecting a cure. Freudenberg of Berlin has recently published a number of such cases in which the patients were materially benefited by Bottini's operation.

Personally, I am still of the opinion that the selection of the route may have to depend upon the merely social question of not interfering with the sexual power, where this point has still to be considered. As far as my own experience goes, the suprapubic operation seems more promising in this respect than the perineal. Three of my patients operated upon by the perineal route have certainly become impotent since the operation, while in none

of the patients operated upon by the suprapubic route has this phenomenon been observed. They all claim to have the power of erection and cohabitation, although the ejaculation of semen has ceased to appear at the time of orgasm in three, evidently due to the interference with the normal condition of the ejaculatory ducts. Perhaps one might say that this preservation of sexual power after the suprapubic operations is a mere chance, and it would be difficult to either prove or disprove this, so long as we do not fully understand the cause of the appearance of impotence, which, by the way, should not be confounded with sterility, as I have pointed out in my last article on this subject. I should not be at all surprised if further observation should show that the trouble is caused, to a great extent at least, by our injuring an important part of the nerve or blood supply in advancing through the perineum towards the gland; also, perhaps, in addition, by the operation as such, which produces relaxation of the normal condition of the veru montanum and the prostatic urethra, both of which are necessary to induce proper reflex action for erection; or, possibly, at last, by our injuring the ejaculatory ducts, which latter accident produces sterility and might, by way of reflex, also produce impotence.

When doing the intracapsular enucleation by the suprapubic route, the disturbance of the nerve and blood supply furnished by way of the perineum, is reduced to a minimum. We also generally do not interfere with the ejaculatory ducts. Only in one case, as stated above, did I pull up one spermatic vesicle into the suprapubic wound, it being firmly attached to the adherent capsule of the lateral lobe.

Summarizing, I beg to offer the following:

1. We have to-day three useful methods for the operative relief of prostatic obstruction, *i.e.* suprapubic and perineal prostatectomy and galvanocaustic prostatotomy (Bottini's operation).

2. Unassailable proof has been furnished to show that all three methods deserve to be recognized as standard procedures, each being capable of bringing permanent relief.

3. Wherever the patient's condition, irrespective of age, seems to warrant it, prostatectomy should be done, since the total removal of the mechanical obstruction naturally represents the most surgical procedure.

4. While it is true that either method, perineal or suprapubic, can be successfully employed to the exclusion of the other in removing the hypertrophied prostate gland, it certainly means facilitating our work and is in the interest of the patient if we use both procedures, choosing in each instance the one that seems best suited to the particular case. The selection of the route, on strict indication, is not an easy matter at present. Further reports by surgeons practising both procedures are needed to decide the question. Both methods are excellent and useful ones. The choice up to the present time is largely a matter of individual inclination. Perhaps we are warranted in saying, on basis of our present experience:

*a.* Glands palpable per rectum and rising not far from the sphincter ani muscles can be advantageously attacked from below.

*b.* If situated higher up and if the growth projects well back into the bladder, they should be enucleated from above, all the more if the cystoscope has shown the presence of a median lobe.

*c.* An hypertrophy of soft character in the early stages, so frequently found to be made up of a number of smaller nodules, each of which can be enucleated by itself, is best attacked from below.

*d.* In the 33 per cent. of cases in which no tumor is palpable per rectum, but in which vesical enlargement is recognized by the residual urine or total retention, and seen distinctly by means of the cystoscope to be the obstructing cause, the suprapubic route deserves the preference.

*e.* If the enlargement be complicated by a vesical calculus or calculi of larger dimensions, too large to be easily extracted through the dilated internal sphincter muscle, the suprapubic route is indicated.

*f.* In patients with very foul urine, where immediate drainage of the bladder is imperative, the suprapubic incision should be chosen. The gland may then be removed at a second sitting.

*g.* The comparatively frequent appearance of carcinoma of the prostate may prove to become an important factor in deciding in favor of complete removal of the gland from above.

5. The question of the preservation of sexual power is an important one. Further experience and investigation are needed to enable us to definitely determine whether there is any difference in results as to this point btween the two methods of operation. As it seems to-day, the suprapubic operation is superior in this respect to the perineal method, even though in the latter the portion of the gland immediately surrounding the prostatic urethra and the ejaculatory ducts have been preserved. If future statistics should prove that with suprapubic prostatectomy the sexual function is more frequently preserved than with the perineal procedure, this must necessarily decide the choice of route in patients in whom this point has still to be considered.

6. If operation with the knife be refused, or there be contraindications to such intervention, Bottini's operation is in order.

7. Only if this operation, too, be refused or impossible are we justified in relegating a patient to the regular use of the catheter.

8. Cystoscopy is absolutely necessary before doing Bottini's operation; it should also precede perineal prostatectomy in order to enable us to determine the presence or absence of a median lobe and calculi; it may be dispensed with if the suprapubic operation has been decided upon, although a previous, distinct knowledge of intravesical conditions must be welcome to the operator. In that 33 per cent of prostatics who present no enlargement on rectal palpation, the cystoscope alone can establish a distinct and refined diagnosis.

9. The time for operation, at least in the rank and file of prostatics, has come when regular catheterization has become imperative. The catheter should never be entrusted to them for regular use. Well-to-do patients, being in a position to take the time and care necessary for the carrying out of self-catheterization on aseptic principles, may be allowed to do so if opposed to operative intervention.

Another strict indication for operation is persistent severe pains in the perineum, neck of bladder and glans penis, resisting ordinary treatment.

10. Surgeons should familiarize themselves with perineal and suprapubic prostatectomy as well as with galvano-caustic prostatotomy (Bottini's operation), in order to be able to do justice to the prostatics entrusting themselves to their care, for no one method of operation can be employed in all cases of prostatic enlargement to the best advantage of the patient. In other words, we must select the operation that suits the case.

# ON THE IMPORTANCE OF DIFFERENTIATION IN THE USE OF ELECTRIC MODALITIES.*

By A. D. ROCKWELL, A.M., M.D.,
NEW YORK.
NEUROLOGIST AND ELECTRO-THERAPEUTIST TO THE FLUSHING HOSPITAL, ETC.

The term Electricity is in a way generic and includes a wide variety of manifestations. In atmospheric electricity we see in highest degree these varied manifestations, magnitude, voltage, with infinite rapidity of oscillation, and the combination is simply deadly in its effects. Man has, in a measure, triumphed over this lethal energy, has analyzed and dissected it, as it were, and made it subservient to his uses, both commercially and therapeutically. In therapeutics we utilize it in the form of the continuous current, one manifestation of which is represented by what is commonly termed the galvanic current with its magnitude and low voltage, the other by the faradic current representing a far higher voltage with negligible magnitude.

Static electricity represents a still higher voltage with practically no magnitude, while high frequency currents are still other manifestations of electric force, with electromagnetic induction effects, kindred to those from the primary circuit of an induction coil, but widely differing in the degree of their physical, physiological, and therapeutic effects. The principles of the ordinary induction coil are here all carried out, the jars taking the place of the cells, with a spark gap instead of a rheotome or current breaker. Like the ordinary faradic current, high frequency currents require for their development some form of initial electric force transmitted through the medium of condensers, coils of wire of varying thickness and length, and like the ordinary faradic current, the relationships of magnitude and tension depend altogether upon the character of the initial force and the intermediate coils of induction. In the same way, therefore, as the faradic current can be made to differ widely in its effects—according to the character of its coils—so, too, with high frequency currents. It is the degree of the step-up process through which high frequency currents are obtained that determines their efficiency, and as there seems to be no uniform constructive standard among manufacturers it is difficult, if not impossible, for different workers to compare results with absolute accuracy.

Now, if there is any one thing more than another that has retarded, still retards and will continue to retard the all round and scientific development of electricity in medicine, it is the increasing tendency to neglect the subject of differentiation in the selection of the various electric modalities. Neglect is but another name for ignorance of the subject neglected, and ignorance leads not only to unsatisfactory therapeutic results, but in the case of so potent an agent as electricity, to damaging results that may be more than transient. I venture to say that the majority of physicians who are doing electrotherapeutic work to-day, whether as a side issue in general practice, or as in some sense specialists along this line, have failed to take a broad and comprehensive survey of the field upon which they have entered, and would be unable to define the principles which underlie the therapeutic uses of this agent.

The individual experiences suggesting these reflections have been many and frequent, one of the more recent of which I beg leave to offer as my text:

A physician who had made much use of electricity consulted me some time ago as to its use in a case of pelvic pain. I suggested the high tension current by the bipolar method. He attempted the treatment but succeeded only in inducing in his patient, a delicate nervous young woman, a most violent tonic muscular contraction. The result was hysteria, increase of pain, and a general nervous breakdown, from which the victim has by no means yet recovered. In addition, the doctor was threatened with legal proceedings, which have been prevented only by much tact, aided by some substantial pecuniary consideration.

In this case the trouble was caused through ignorance of the relation of quantity or volume, and tension, and the measure of their combined or respective influence on living tissue, together with unfamiliarity with the mechanism of the apparatus employed. It was desirable to produce a sedative effect through the use of the high-tension coil. To secure this effect and avoid injury in the application of the varied manifestation of inductive energy, one must appreciate the fact that, through high resistances such as the skin, the high tension current exerts a vigorous action, while an induction current of low tension through the high resistance of the skin, acts much less vigorously. On the other hand, when applied through the low resistance of a mucous membrane, the high tension current acts with little vigor so far as muscular contractions are concerned. Its efforts are gentle, sedative and barely perceptible.

On the contrary, the induction current of low tension and increased magnitude acts as powerfully through the low resistance of the mucous membrane as do high tension currents through the high resistance of external surfaces; but producing effects that are irritating and decidedly painful.

A little personal experimentation will readily convince one of the striking difference in the action on nerve and muscle of these varying combinations of magnitude and tension. It is very easy accidentally to demonstrate this principle to the injury of the patient, and the astonishment and chagrin of the physician. This is what may very readily occur, and what actually did occur in the case above recorded. A bipolar application with the current of tension is being made to some one of the mucous surfaces. The patient complains of an uncomfortable sensation which may or may not be due to the action of the current, and the slide is shifted so as to exchange the current of great tension but negligible magnitude, for one of lesser tension but appreciable magnitude, which, according to all the experiences of external application, is infinitely weaker. Instantly a shock is occasioned, associated with the acutest pain and rigid contractions, that astonishes the operator and terrifies the patient. In all this reference is made to that much neglected, but eminently useful modality commonly termed the faradic current, the physiologic and therapeutic action of which varies within its range of power in the same way as do high frequency currents. In the use of the latter, I have had frequent occasion to differentiate between its various manifestations, and have seen illustrated in a very positive manner, their relative therapeutic as well as physical effects. It will be conceded that nutritional effects in greater or less degree attend the use of every electric modality; it is indeed this fundamental idea of its nutritional effects upon which in great measure must be based its utility in medicine. That it works both ways—that alternating currents of high voltage may disturb as well as improve the processes of nutrition, has been recently observed among the employees in

* Read before the American Electro-Therapeutic Association, September 19, 1905.

great powerhouses, where, exposed for long periods of time to such influences, grave functional disturbances of nutrition are not infrequent. My own use of high frequency currents has been mostly with static electricity as the initial force, connected with the ordinary condensers, and for the primary and secondary coils, wires respectively 25 and 200 feet in length. It seems to me, after a considerable experience, that with this arrangement we get the two extremes of high frequency effects that will accomplish about all that can be expected from more elaborate combinations. The current from the secondary coil with its tension and enormous frequency but without magnitude yields, as one would naturally infer, results that are quite superficial; valuable for its effects upon the periphery, but much less efficient so far as constitutional or deep-seated nutritional effects are concerned.

The current from the primary coil with lower tension and frequency, but with far greater magnitude, not only influences the periphery and superficial skin lesions, but exercises a distinctly deep-seated nutritional effect. An interesting confirmation of this fact was recently observed in a case of pseudohypertrophic muscular paralysis. Now, muscular paralysis of this type is admittedly an incurable disease. During the course of my experience a number of such cases have been subjected to a thorough course of electrical treatment, including continuous and static methods, but never with the slightest benefit. The developmental tendency to tissue growth, which is its essential element, has thus far baffled every effort. While, like locomotor ataxia, this disease is progressive, there is often seen, as in the latter condition, periods of retardation and apparent arrest, so that certain drugs, such as arsenic and phosphorus, have been supposed to exert a distinct influence in temporarily, at least, arresting the progress of tissue growth, but thus far there has been no satisfactory proof that this arrest is anything more than a part of the natural course of the disease. What has interested me in two cases that have come under my observation, was not simply an apparent arrest, but a very positive improvement under the influence of high frequency currents of magnitude, administered not by the indirect method of D'Arsonvel, or the method of autoconduction as it has been termed, but by the administration of the spark itself by the direct bipolar method. This improvement manifested itself in three pronounced ways; First, by the ability of the patient to get in and out of a street car without assistance, something that she had been unable to do before in the progress of the disease, for the past six months; second, in the ability to walk unaided without frequently falling; third, in such an increase of power over the waist muscles as to enable her, when bending far over, to raise her body to the erect position without the aid of her hands.

Further progress has not been and in all probability will not be attained, and the progress of the disease will not be permanently checked, but the case illustrates in a very interesting way the superiority of a magnitude over pure tension and frequency in influencing the nutritive processes, and is but another illustration of the importance of differentiation.

The rationale of the superiority of currents of magnitude in not only ameliorating the symptoms of many organic conditions, but aiding in the cure of deep-seated congestive conditions, may be explained by its superior vasomotor influence with relief of blood pressure, improvement in nutrition of degenerated nerve cells and consequent development of potential energy.

The superiority of the continuous current of magnitude (galvanic current) over all other manifestations of electricity for the relief of inflammatory exudates, is, or ought to be, too well known to need any emphasis of mine. And yet it is not uncommon to find physicians using other forms of electricity and especially high frequency currents, in the belief that they were utilizing the best methods; forgetting that the rationale of the action of electricity upon all inflammatory exudates, is based upon chemicophysical action, and that in the continuous current of magnitude alone do we get appropriate and satisfactory electrolytic and absorptive effects. In discussing the admittedly difficult subject of differentiation, there is one combination of electric forces that deserves consideration. I refer to combined electrization or the transmission to the body through the same electrodes of the direct and to and fro currents, (the galvanic and faradic). To determine its distinctive value is certainly more difficult than to differentiate between the individual modalities of electricity. It is very much a question of practical experience aided in some degree by our knowledge of the physical and physiological action of the various modalities. Each of them possesses a certain limited power to relieve pain, one succeeding where another fails, and the reason for success or failure, can often be accounted for through misapplication—the application of stimulating effects where sedative effects are called for and *vice versa*. Combined electrization is not efficient for the relief of pain in any such degree as the various single manifestations of electricity. On the contrary, it is more likely to increase than to decrease any form of pain, simply because its combined mechanical and chemical or electrolytic action is bound to act counter to the effect desired, whether it be sedative or stimulating. On the other hand, its musculosedative effects are pronounced, rendering it distinctly more valuable in the relief of spasmodic conditions than any single modality. The superior effects of galvanofaradization in the treatment of constipation and enterocolitis, which I have often observed, and which have been emphasized by some others, notably by Bordier and Delherm, I am inclined to attribute to this control of muscular spasm, which is believed to be a not infrequent accompaniment of intestinal atony.

616 Madison Avenue.

## ATONY AND ASSOCIATED PATHOLOGICAL CONDITIONS OF THE RECTUM AND COLON, WITH MECHANICAL METHODS OF TREATMENT.*

By FENTON B TURCK, M.D.,

CHICAGO, ILLINOIS.

Probably one of the most universal complaints met by the practitioner is atony of the lower bowel. The term atony signifies lack or loss of contractile power. The following terms are also used to indicate this condition: Motor insufficiency, myasthenia (muscle weakness), idiopathic dilatation, paralysis, etc. The term atony is an old one, but has been especially emphasized by Todd, and the condition it expresses been called by various names, according to what each author considered to be the most important symptom or condition.

Atony is characterized by a deficiency or failure of peristaltic action. Before we can comprehend the full significance of atony we must have before our minds the normal condition or physiology of peristaltic motion. Briefly stated, it is a coordinated

*Read at a meeting of the Missouri Valley Medical Society at Council Bluffs, August 24 and 25, 1905.

rhythmical muscle contraction. Rhythmical contraction implies alternating contraction and relaxation, whereby the contents of the bowel are propelled onward. If the muscle wall of the colon remains in a relaxed state or in a contracted condition, stasis of the contents results.

Tone implies a state of moderate degree of contraction constantly present, and is essentially associated with normal peristalsis.

*Physiology of Peristalsis.*—Without discussing the myogenic or neurogenic theory of peristaltic movements, we may state that the principal cause of bowel movement is the bowel contents, and as Illoway concludes: "Still the principal factor of peristalsis here is the coarse particles of the undigested food residue." Nowak and Brautigam[1] regard the flatus as the important stimulus to peristalsis, by the distention of the intestines. I have found experimentally that peristalsis is promptly excited by distention with air, and that in the beginning the contractions are confined to the area of such distention.

In experiments on dogs, by inserting a small rubber bag attached to a tube through an opening made in the bowel, I found that on distending the bag different areas of the intestines varied much in the promptness with which contractions took place. The upper part was more responsive than the lower —the colon the most sluggish in its response.

The mechanical factor of distention enters largely into the causal relation of peristalsis of the intestines, and this is also in accordance with what I found experimentally in the stimulation of gastric movements.[2] That other factors—such as those of psychical origin—may also originate intestinal peristalsis, we have considerable clinical evidence.

Cannon observed experimentally that inhibition of peristalsis occurred when the animal was teased or tormented. Nothnagel[3] states that "mechanical irritation is a palpably necessary factor for the excitation of peristaltic movements." We may safely conclude that whether the distention is with air, gas, water, feces, or accumulated mucus, peristalsis is evoked.

*Pathology.*—In atony of the intestines, according to Nothnagel, "the driving power of the intestinal wall becomes insufficient, the contents of the affected segment of the intestine become stationary and are not propelled onward, stasis of the bowel contents and accumulation of fecal material naturally occur. Where this occurs all the processes and conditions seen in cases of mechanical obstruction of the intestines develop."

Bodenhamer[4] holds that by distention of the bowel causing atony no irreparable damage is done. "Neither is it a true paralysis, such as occurs in paraplegia, but is merely a local impairment of muscular contractility"; and he further regards this deficit of muscular power in the rectum "the result of prolonged distention of its walls."

*Experimental Observations.*—It will naturally occur to anyone to inquire what transpires in the muscle wall during such local distention, as frequently results from failure to "attend to the calls of nature." In my experiments with dogs, I found that by keeping up intermittent distention of the hollow viscera without a sufficient period of rest, fatigue and finally marked dilatation would result. The stomach would not recover for several days, while the small intestine would recover far more promptly. The colon, when fatigued, was slow in recovery, the lower portion especially.

It required five to seven hours of intermittent distention to produce complete fatigue; this accomplished, the viscera were removed, ground up and the fatigue toxin extracted. Injecting dogs with the toxin thus obtained produced fatigue and dilatation similar to that obtained by mechanical means. An antitoxin was obtained which neutralized the fatigue toxin both *in vivo* and *in vitro*. Since my first publication[5] of these experiments, Weichert[6] has obtained similar results in general fatigue, showing that the laws of fatigue of striated (voluntary) and unstriated (involuntary) muscle, if not identical, are closely related.

The cause of fatigue is evidently a toxin formed during muscular action, which produces only local effects because the toxin of fatigue is not dialyzable (Weichert), and remains in contact with the muscle. The antitoxins usually form and neutralize the toxin during the rest period. Massage hastens the process —the union of the antitoxin with the toxin.

*The Relation of Atony to Fatigue.*—The terms used to signify this process are numerous, but mostly represent the same idea. Thus Nothnagel speaks of the condition as a "fatigue"; Hemmeter, an "exhaustion"; Riegl, a "weakness" of the muscle wall; and T. Lauder Brunton[7] says "feeble," and "hangs down much lower than it ought to." The site of atony is usually found in hollow viscera, where resistance to muscular contraction is greatest. This is in cavities used as reservoirs—such as the stomach, colon, urinary bladder, and gall-bladder. Conducting tubes which convey the contents are not so subject to fatigue, as each segment put upon a strain in removing the load is placed at rest as soon as the contents are propelled onward, hence no fatigue of the muscle occurs, no atony, and consequently no retention.

Retention within certain limits of time and quantity is the normal condition in hollow viscera designed as reservoirs and cisterns. If accumulation occurs from any cause, producing distention beyond the normal resistance or beyond the normal limits of time, fatigue toxins form in greater excess than their respective antitoxins, and what we call atony is the result.

Prolonged and excessive distention produced by any substance that will stretch the muscle and excite contraction or attempts at contraction will ultimately result in overwork and fatigue. This may be brought about by air, as shown by my experiments, or by gas, as shown by Nothnagel, food, liquid, or the end products of digestion. Boas[8] says: "Habitual constipation, over-distention of the ampulla recti, gradually leads to paresis of the rectal muscle and sphincters." Nothnagel says: "At all events, in habitual constipation, the stasis of fecal matter is always limited to the large intestines, or at least originates in this portion of the bowel."

The conclusions I am forced to make, founded on experimental and clinical observations, are:

1. That atony, fatigue, or exhaustion is due to a toxin which renders the muscle atonic, a loss of tone, and of peristaltic energy.

2. That fatigue is produced by "overwork," such as distention or stretching without adequate rest.

3. That no exhaustion exists—nothing is lost, but the toxin is formed which inhibits the normal cell action.

4. That the toxins are neutralized by the antitoxins formed during the rest period.

5. That excessive toxin or a reaction insufficient to produce the antitoxin results in fatigue.

*Disturbed Circulation of the Splanchnic (Abdominal) Vessels.*—My experiments with various agencies, both chemical and mechanical, causing dilatation of the stomach and intestines, showed that atony and dilatation produce marked disturbances of circulation, especially of the abdominal vessels, and, on the other hand, congestion of the abdominal circula-

tion profoundly inhibits the peristalsis of the hollow viscera.[9]

Von Braam Hockgeest[10] and Nasse[11] have shown that venous stasis inhibits peristalsis of the intestines. Fatigue of any muscle occurs more readily in the presence of venous stasis. Recently Weichert[12] found experimentally that muscle becomes more easily fatigued in the presence of carbonic oxide, and oxidation deprives the toxin of fatigue of its virulence.

We may conclude that the important factors to be considered in atony are: (1) The fatigue of the muscle wall of the intestine; (2) the congestion of the intestinal blood-vessels.

*Secondary and Associated Pathological Conditions.*—One of the innumerable secondary results or associated conditions of atony is constipation, or constipation alternating with diarrhea. The atony with constipation produces a condition demanding special attention, namely, that of hemorrhoids. This is emphasized by nearly every author on the subject. The pressure of the fecal mass upon the hemorrhoidal vessels, and the increased intraabdominal pressure in the effort to expel the bowel contents persistently obstruct the return flow in these veins, lead to dilatation of the vessels, and result in hemorrhoids.

Since the hemorrhoidal veins contain no valves, when the perivascular support is lost through atony of the bowel, they necessarily give way under the pressure and form a sacculated or varicosed mass. Eichhorst noted the hemorrhoidal formation in persons playing wind instruments, caused by the more or less constant increase of the intraabdominal pressure.

*Rectal Prolapse.*—A frequent complication of hemorrhoids is rectal prolapse. This is especially noted where these atonic conditions are well marked; usually the mucosa alone is involved. Procidentia recti (prolapse of all the coats), with or without hemorrhoids, is usually found where there is extreme relaxation of the ligamental supports of the rectum, combined with atony of the levator ani and muscle walls of the bowel.

A form of intussusception occurs when the upper portion of the rectum telescopes down through the lower part without protrusion through the sphincter. When atony is extensive and extreme, involving the sphincter, the rectum presents at the anal orifice, gradually assuming a permanently prolapsed condition, with ulceration and inflammation of the protruding mass.

*Enteroptosis.*—Rectal prolapse is frequently but a part of general prolapse (splanchnoptosis). Some individuals are more inclined to prolapsus than others—a congenital defect. Thus we have a type recognized by all clinicians, which possesses a "predisposition" to gastroenteroptosis. There is a large class which acquires the condition of ptosis of one or more of the abdominal organs. This subject (splanchnoptosis) is engaging the attention of both physicians and surgeons throughout the world—a fierce controversy having arisen among different observers. Surgeons look upon the ptosis *per se*, the postural anomaly, as the chief factor accounting for the general and local disturbances. Kemp[13] has recently concluded that prolapse of the gastrointestinal tract is a powerful factor in the production of many nervous disorders. Regal [14] has frequently noted the total absence of all symptoms, abdominal or general, in gastroenteroptosis. He does not regard the postural anomaly as the cause of the nervous disturbances.

Kussmaul regarded as the cause of the symptoms a perversion of motor power. Hemmeter,[15] after a careful review of the literature, concludes that "the symptoms are brought on by the gastric and intestinal atony"; and that enteroptosis is not an anatomical process.[16]

*Summary.*—1. Clinically, anatomical displacements are frequently without symptoms because no fatigue or atony exists.

2. Where symptoms arise, they are usually due to atony or fatigue.

3. Correcting the atony or fatigue of the intestines results in disappearance of symptoms, except in atrophy or the presence of actual obstruction.

4. "Predisposition" to this condition may be considered as a deficiency in the resistance of the body, which in the modern idea is a deficiency of formation of antitoxins or "antibodies."

*Diagnosis.*—There are many means of diagnosing atony of the colon. One is the symptomatic. Constipation is the most common symptom, but diarrhea is also a symptom of atony; or, again, we may have no marked difference in the frequency or apparent character of the stools. Some cases of atony with marked toxic symptoms that I have noted are in those who have asserted that their bowels are as "regular as clock-work." Examination frequently showed a residue always present. It is not the purpose here to discuss the various methods of diagnosis, but we may state two of greatest value: (1) The examination of the feces removed from the bowel through the tube, during colonic lavage; and (2) the reaction of the colon to the stimulus of distention.

The chemical and microscopical examinations are of great importance, especially after certain test meals, but frequently I can determine better the condition of the peristalsis, etc., by the gross or macroscopical appearance of the discharge through the tube, whether flat or round, hard or soft, sand-like bodies or mucus, etc. It is important to know the distribution of these masses along the colon; whether the accumulation is in the sigmoid, high up or low down; and to note whether the rectum is transformed into a reservoir instead of remaining a canal. These determinations are largely a matter of experience.

The manner in which the colon acts after distention with air—the local puffing up in the region of the sigmoid, the ballooning of the rectum, and the dilatation of the cecum, are all of value in determining the degree of the resistance of different portions of the colon. Hence the degree of atony can be fairly well estimated. The degree of force with which air returns through the tube or escapes alongside of the tube, and the action of the sigmoid give valuable data.[17] If, on pressing out the air from the sigmoid, peristalsis soon follows and the residual air escapes through the tube, there is not such a high degree of atony as in other cases where no such results are observed.

In colonic lavage similar observations may be made, and differential diagnosis determined between spastic contraction producing obstruction and simple atony without spasm. The differential diagnosis is important to make in order to carry out the line of treatment best suited to each condition. While spastic contraction is an expression of an atonic state of the colon, it requires a modification of the treatment of simple atony without spasm of the bowel.

*Treatment.*—In the treatment of atony of the intestines with associated disturbances, such as prolapses, hemorrhoids, and pathological conditions of the mucosa, various methods have been utilized—many of great value, while some have been total failures. The treatment by mechanical means, such as gymnastics and massage, is more generally applied to strengthening the abdominal walls than directly affecting the muscle wall of the intestines.

Nothnagel[18] contends that while the strengthening

of the abdominal muscles by massage and other exercises materially aids the individual in the act of defecation, it exerts no material influence upon peristaltic movement of the intestine. In prolapse and dilatation, surgical measures have offered considerable promise in eradicating the difficulties, such as taking up the folds in prolapses, stitching up the sigmoid—all of which are valuable in so far as they correct flexures; but atony is a disease of the muscle wall, and even excision of the entire sigmoid has been attempted,[19] with the result that within fifteen months' time a new sigmoid flexure developed, which filled the lower part of the abdomen.

In cases of obstruction produced by tumors, cicatrices, and adhesions, the obstruction must be removed by surgical means. In some forms of extreme atony with infection, the colon can be best placed at rest by right-sided colostomy—until the restoration is complete.

The treatment of atonic state of the colon is usually divided into that of dietetics, physical, mechanical, and medical treatment. By careful analysis of most methods in vogue it will be seen that in reality they are mostly of a physical and mechanical character. Coarse-grained food depends for its action largely on its mechanical effect, that of distention.[17] Bran, which is chemically inert, furnishes bulk and excites movement, by the same means we employ in the laboratory experiments on animals, viz., distention, or, to be more technical, *tension*, followed by a release of the tension. If the substances which produce such tension are of such a character that they are moved onward, releasing the tension of the segment where such tension is produced, then peristalsis continues without fatigue; but if such is not the case, and the tension is continued for any reason, fatigue ensues and atony is increased.

The increased production of gases and quantity of fluid is another mechanical factor in certain forms of diet used to excite peristalsis. Many drugs owe their value largely to the mechanical stimulus which they induce through increased secretion. Drinking water in large quantities has a similar effect. Instead of drinking water or exciting the secretion, fluid is frequently injected into the bowel. Distending the bowel, as we have seen, causes prompt response.

In order to avoid the evil effects of over-distention with water, I have for many years allowed only a small quantity of fluid to enter the bowel at a time—100 to 300 c.c.; then disconnecting the reservoir, this fluid is allowed to escape through the tube, as in lavage of the stomach. By increasing the temperature according to the condition, a high degree of stimulation is obtained. By repeating the process, we produce a form of exercise for the colon.[20] In weakened and atonic conditions, the water used even in the manner described is not all recovered, but remains partly in the bowel; this results in fatigue, and tends to increase the atony. By inflating the bowel with air and pressing upon the abdomen, the air is forced out.[17] Repeating this a few times, peristalsis is induced, and the water may then escape from the bowel through the tube. By connecting the tube with a Politzer bulb and alternating compressing the bulb and releasing the pressure, the entire column of air as far as the cecum is set in a vibratory motion, which excites peristalsis.

In some forms of atony it will be noted that when the sigmoid is distended with air directly, the air remains in the sigmoid, even when the tube is left open, as the walls are too weak to force out the air. If the air is allowed to remain, fatigue will result, but if the sigmoid is pressed upon from the outside over the abdomen the air is forced out, or a good portion of it, the result being a stimulation to contraction (peristalsis). In a large proportion of cases even this is not possible to attain by the direct method; therefore the indirect method of exercising the colon (as devised by me and in use in my practice for the past ten years) is attempted, and that is done by first introducing a small, thin, rubber bag attached to a tube into the bowel, then inflating the bag with a Politzer bulb, thus moderately distending the viscus, and then releasing the pressure, all the air escaping promptly;[21] thus no fatigue occurs, but instead a stimulus to contraction. If this is repeated, the colon receives a high degree of exercise without fatigue, which in time corrects the fatigue and atonic condition.

Not only does this mechanical method produce valuable results in weakness of the muscle walls of the intestines, but, as would naturally follow, it acts as massage to the mucous membrane, and is of excellent service in hemorrhoidal conditions of the rectum.

In prolapse of the mucous membrane it has proved useful. In prostatitis and some bladder disturbances the gentle massage and exercise have given excellent results. Each distention not only raises the walls of the bowel, but during the inflation the surrounding viscera are also lifted up by the pressure. It would suggest itself as a useful means of treating the pelvic organs of both male and female. In retrodisplacement and prolapse of the uterus this method has been found of great service. Before entering into a discussion of the application of this method to the associated pathological conditions in atony of the colon, it will be necessary to describe the apparatus and its technique in application.

We usually use three different forms of rubber bags—fusiform, pear-shaped or round (Fig. 1) or double sphere with double tube (Fig. 2), one leading to each bag or balloon, according to the location in

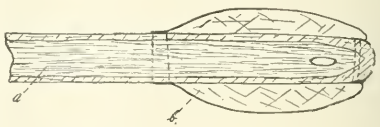

Fig. 1. Single tube (*a*) with bag (*b*).

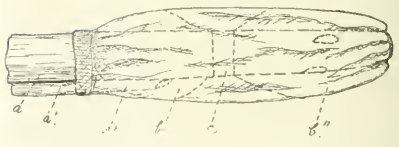

Fig. 2. Double tube; *a*, large tube; *a'*, small tube; *b*, bag, with band at (*c*) dividing into compartment *b'* and *b''* as per dotted lines.

the intestine where it is to be applied. The size of the bag varies also according to the special use desired. In large dilated conditions the larger size, such as used in the stomach, may be of service. In sensitive and nervous conditions a large size may be used at the outset of treatment, but as very little tension is desirable, only partial inflation is used.

The small sizes are used where greater tension is desired, the inflating of the bags causing a firmer degree of pressure upon the walls, but a lesser degree of excursion of each motion.

The degree of thickness of the wall of the bag makes considerable difference, whether used for distention of the muscle wall or the massage effect upon the mucous membrane of the intestine. The thin bag will produce less massage or rubbing upon the mucous membrane.

Bags may be improvised by using thin finger cots

for the purely gymnastic effect; thicker ones for massage purposes.

The tube is made of red rubber, with end and side opening. The caliber of the tube and thickness of the wall are sufficient to prevent occlusion. A large-sized catheter, or a small-sized stomach tube will do. The rubber bags are attached to the tubes by tying with silk. The double tube is used for special purposes.

Bags made for me are attached to the end of the tube in the same manner as my intragastric bag,* so as to prevent buckling, and also tied to the tube at the neck of the bag with silk. (The thread may be covered by folding back the neck). The bag is inflated with air by an eight-ounce Politzer bag with a valve.

I have used compressed air at a low pressure of two or three pounds, connected with a manometer, but have found that the hand method with the Politzer bag is more satisfactory.

When the bag is inflated to the desired degree of distention, the finger is placed over the valve opening of the Politzer bag. Compressing the bag and releasing the pressure will cause alternating distention and partial collapse of the bag inside the bowel.

*Technique.*—If the lower portion of the rectum is to be treated, the bag is oiled and inserted, care being taken not to have the tube bend upon itself. It is frequently of advantage to use local medication with ointments or medicated solution in slippery elm emulsion. Should the sphincter be tightly contracted so the bag cannot be introduced, gentle massage of the anus externally with vaseline or a little green soap will cause the muscle to relax.

On first inflating the bag, sudden pressure must not be exerted, but gradual distention, as sudden expansion may cause distress. As soon as the bag is slightly distended, the air is allowed to escape, and this is repeated a few times, with no pain or distress to the patient. By gradually distending the bag with air until say one or two Politzer bags full of air have been introduced, then by alternately pressing the Politzer bulb and releasing the pressure the exercise of the rectum is produced. If it is desired to reach the bowel in the region of the lower portion of the sigmoid, the tube can be directed alongside the finger upward above the promontory of the sacrum, or inserted through the sigmoidoscope, the bag being held in this position by holding the tube firmly against the sphincter, or by author's self-retaining attachment for rectal tubes. The double bag with double tube, however, is especially designed for the purpose of the gymnastic exercise of the sigmoid. The proximal bag is first inflated, in order to hold the tube and distal bag high up in the colon, and then the Politzer bag is connected with the tube leading to the distal bag. The gymnastic exercise can then be accomplished as desired through this distal bag.

Slow distention or small, rapid vibrations may be used in the exercise, as an apparatus may be attached which will give rapid vibrations when desired. The treatment then consists of:

1. Slow, intermittent movements of considerable displacement or distention, using a full eight ounces of air in the Politzer bag.

2. Rapid vibrations either compressing the bulb with the hand or with the special apparatus.

3. Massage of the mucous membrane by the friction of the bag against the wall of the intestines.

The physiological action of the method is to produce (1) local effects by the distention and relaxations; (2) reflex effects.

*A bag with a small socket at the bottom has been made under my directions for years, and is found in the catalogues of dealers in instruments and rubber goods. Some concerns reinforce the socket.

1. It excites muscle contraction (peristalsis) of the wall of the intestine.

2. It causes contraction of the sphincter.

3. It stimulates the local circulation.

4. The pressure and effect on the circulation have a salutary effect upon the glands of the mucosa.

5. By inserting an extra bag connected with a manometer the increase of pressure in the rectum is shown to be 10 mm. to 15 mm. Hg. of distention over normal.

6. Inserting the stomach bag of the gastric motormeter[22] into the stomach, during each compression of the Politzer bulb, and distention of the rectal bag show corresponding effects.

*Massage.*—1. By the friction back and forth the muscles receive a massage effect.

2. The mucous membrane is massaged; débris of cells and mucus is removed from the surface, the same as is attempted by the application of solutions of nitrate of silver. This treatment restores the normal sensation to the mucosa, the loss of which accounts for many cases of constipation. The painful and nervous state frequently observed in these cases is much relieved by this massage method.

The deep and superficial hemorrhoidal veins are markedly affected, the friction with pressure emptying these vessels, and gradually the tone of the venous wall and supporting tissues is restored; for, as Recklinghausen has clearly stated: "Fluid contained in a flaccid and dependent sack (varicosed hemorrhoidal veins) always sinks to the bottom; thus dilatation and elongation of this sack occurs." The greatly increased tone of the hemorrhoidal veins produced by the use of this method soon overcomes the varicosity, and there is gradual absorption, with complete disappearance of the hemorrhoidal condition.

Where true benign tumors (angiomata) of the character described by Reinbach[23] with sclerotic tissue are found, such must be removed by surgical means.

*Effect on the Pelvic Organs.*—If the hand is placed upon the abdomen it will rise and fall with each intermittent distention of the intracolonic bag, as the bladder rises and falls during each inflation.

In making a bimanual pelvic examination, while an assistant operates the Politzer bag, it is observed that the uterus is lifted upwards and forward in the pelvis, thus affording a very effectual and practically painless method of obtaining massage, and at the same time strengthening the suspensory ligaments and other supports of that organ. Partly through the effect of direct massage, and partly through the stimulation of the blood supply of the pelvic viscera, the nutrition of the ovaries and uterus is greatly benefited. By the direct pressure upon the prostate and seminal vessels a delicate and valuable massage effect is obtained.

*Reflex Effect.*—By the alternating increase and decrease of the intraabdominal pressure, the splanchnic circulation is affected, and when combined with the vasomotor reflex upon the medulla we obtain a valuable stimulation of the general circulation. The reflex effect obtained by this method is analogous to that of stretching the rectum, which has been useful in collapse. There is also obtained the stimulating effect of pressure exerted upon the sympathetic ganglia.

The heart is usually slowed 10 to 15 beats on the distention of the bag in the rectum, and acceleration follows. The blood pressure is raised 10 to 20 mm.

In sigmoiditis with prolapse and retroversion of the uterus, which are frequently associated, the symptoms arising in these conditions are usually due to atony, and not to the mere displacement. The con-

gested condition of the circulation is a part af the clinical picture; one, therefore, can readily understand why correcting the atonic conditions of disordered circulation will have much to do in restoring many of these sufferers to a condition of health. In carrying out the treatment it would be necessary to appreciate the application of the method to the different conditions, thus, where we wish to produce exercise of the muscle wall we may use a thin rubber bag, but if we wish to get more powerful direct massage effect upon the mucosa, we would use a bag of thicker rubber.

Where we wish to correct hemorrhoids, especially those forms which tend to prolapse, we may in certain cases use to advantage the double bag and tube, one bag internal, and the other remaining external to the sphincter. Both bags are inflated. On compressing the Politzer bag leading to the inner bag, the outer one is drawn upward, compressing the sphincter.

These methods are not presented with the idea of exclusion of any of the present methods of treating many diseased conditions of the rectum and colon, but are offered as an adjunct which for years I have found to be of great service.

It will not be practicable to give detailed reports of the many cases treated, as they will be presented in separate communications. The following illustrative cases, however, may be of interest, as they combine several associated pathological conditions with atony of the colon:

Mrs. F. S. W. was referred, suffering from pain in the lower abdomen, emaciation, and general weakness. She had alternating constipation and diarrhea for several years. She complained of uterine trouble, including dysmenorrhea, for which she had been treated locally, having worn a pessary with no beneficial results. Medical treatment had failed. Sanatorium treatment, rest, external massage, and baths produced no improvement in the symptoms. Examination showed general loss of nutrition and anemia. She was tender over the region of the descending colon and sigmoid, which was dilated. The uterus was retroverted and prolapsed; enlarged and tender to the touch; no adhesions. There were sigmoiditis, proctitis, and internal hemorrhoids. There was a mucomembranous discharge from the bowel. Before instituting treatment, Dr. C. S. Bacon was called in consultation for gynecological examination. Treatment was then carried out by daily exercising the colon with the thin, soft rubber bag inserted behind the uterus through the rectum. At first the least pressure excited pain and nervous symptoms. By cautious and slow distention, increasing the pressure each time gradually, the painful symptoms lessened, until no distress or pain was experienced.

After each treatment there was noted an improvement in the general circulation. At the end of one month's treatment there was general improvement, and the movements of the bowel were more regular and improved in character. The treatment was three times weekly for two weeks, after which treatment was given twice a week. At the end of two months the patient had gained in weight and complained of no uterine or bowel trouble. Examination showed a retraction of the dilated sigmoid, a disappearance of the loose, flabby condition of rectum, and no pain on pressure anywhere in the pelvic region.

At the end of ten weeks no mucous discharge; no constipation or diarrhea; disappearance of the hemorrhoids. The uterus retracted; the fundus no longer pressed upon the rectum. No further treatment was carried out.

In one year after the patient was again examined, and no uterine symptoms or pathological conditions found. The patient recently examined, three years after, shows the excellent results obtained are permanent, and without any subsequent treatment.

An interesting point in the above case is that not only the atonic condition of the bowel disappeared, and the uterine trouble, but the mucous membranous colitis did not return. This result I have obtained in most cases. This may be partially, if not wholly, explained by the recovery from the atony and relief from the constipation, as Dommer[24] recently concluded that membranous colitis is the result of atony with constipation. The cause of mucous colitis has recently been studied post-mortem by Elsner,[25] who found that atony and obstipation were the chief factors in producing the condition.

The following case, Mr. A. C. O., aged fifty-two years, was admitted to the Institute, suffering with severe rectal prolapse, internal hemorrhoids, and proctitis. The prolapse included all the layers of the rectal walls, with protrusion. The condition had gradually grown worse for ten years, and in the last three years the patient became a nervous wreck, losing in that time twenty-five pounds. Had not been able to attend to any work for two years previous to his coming to Chicago. Obstipation, with well-defined autointoxication symptoms. Frequent spells of vomiting. When movement of the bowels was forced by drugs or enema, symptoms of collapse followed. The rectum protruded two to three inches, with prolapse of part of the muscle coat. When the protruded bowel was replaced, walking across the room resulted in prolapse; dilated sphincter, with loss of control. There were proctitis with infiltration; three large hemorrhoids, one of which was indurated; general varicose condition of the veins of the rectal mucosa; a chronic ulcer. Operation refused. Treatment was instituted by pneumatic exercises with rectal bag. Treatments were given each morning by very slow and partial distention of the bag in the rectum. Gradually the local painful symptoms disappeared, and more active treatment was instituted by increasing the distention of the bag with air and using more rapid vibrations.

A gradual improvement was noted each week. Treatment was suspended at the end of two weeks for three days; then resumed every other day for one month, with an intermission of one week. The treatment was continued again two or three times a week, another month.

The improvement continued, and the patient left the city for a visit, and returned in three weeks. The treatment was resumed for another month, with continued improvement of general health, as well as local conditions. The bowels moved regularly without drugs or enemata. The rectum did not protrude and the prolapse was reduced. The hemorrhoidal condition disappeared, except the large indurated hemorrhoids, which were removed surgically. Recovery was complete.

The following case shows the relation between diseases of the rectum and prostate: M. F. E., sixty years; widower. Suffered for six months before examination with intense nervousness, hemicrania, insomnia, and fainting spells. Frequent micturition. A mucopurulent discharge from the urethra. Loss in weight, twenty pounds. Three years before had "nervous prostration," with rectal disturbances. After-treatment both local and general for six months; recovered. Treatment of present condition had failed to bring any relief.

Examination showed mucopurulent discharge from urethra. No history of exposure. Microscopically: Leucocytes; epithelial cells; a few diplococci (extracellular); no pus organism; no tubercle bacilli; bacilli resembling colon bacilli present. Re-

peated examinations failed to identify gonococci. Anal sphincter dilated and prolapse of mucosa; ulcer, hemorrhoids, intense hyperemia; very sensitive to touch. Prostate enlarged; soft; hyperemic. Prolapse of the sigmoid. Rectal enema increased the suffering.

Treatment by internal pneumatic exercise of the rectum and colon was carried out daily. At first the pain and nervousness of insertion of the soft tube made progress slow; soon a tolerance was induced, until no distress accompanied the treatment. Rapid progress followed. At the end of six weeks the urethral discharge stopped, without giving any intraurethral treatment or drugs. All symptoms disappeared at the end of two months. The action of the sphincter returned. The hemorrhoids and ulcer disappeared. The prolapse and atonic condition of the bowel retracted, and all tenderness and pain subsided. The hyperemic condition of the prostate was reduced. The excellent results obtained in this case were evidently due to the local exercise and massage.

Mr. D. S. G., sixty years; height 6 feet 1¾ inches; weight 155 pounds. Complained of indigestion, nervousness, insomnia, anorexia, great depression, and weakness. Loss in weight, 35 pounds. The physician referring the case was his son, and reported that the patient in his younger days had not suffered from any neurasthenic symptoms. The usual line of treatment had produced no results. Exploratory incision had been suggested, but refused. Briefly abstracted from the history sheets, the following conditions were found: Heart, liver, kidney, stomach, and small intestines negative. Examination by the rectum showed prolapse of the sigmoid and upper portion of the rectum. Marked atony, with sigmoiditis and proctitis. Mucous membranous colitis. Rectal ulcer; hemorrhoids (internal). Great tenderness. Could not sit down without the use of an air cushion. Treatment was mechanical. Pneumatic exercise of the rectum and colon by both direct and indirect methods. Use of the rectal rubber bags. Improvement was constant. Discharged August 8. Weight, 165 pounds. All symptoms disappeared, as well as the pathological conditions. No drugs or surgery were found necessary. One year after, August 8, report shows weight, 190 pounds—gain, 35 pounds. Patient without symptoms. Recovery complete.

*Contraindications.* — The contraindications are similar to those of lavage, but in fact we may use air where lavage with water cannot be used. I have for many years utilized the great benefits derived from the application of the distention of the hollow viscera with air without harm. Inflation of the stomach and intestines has long been used, principally for diagnostic purposes. My experience coincides with that of Regal,[26] who states: "I have performed artificial inflation daily for a long time, and have never seen any disadvantages or any serious symptoms from this method."

*Conclusions.*—(1) Atony of the intestine is a failure of the normal function of muscle coat.

(2) The principal cause of normal peristalsis is the distention produced by the bowel contents, whether that be feces, or undigested food, water, gas, or air.

(3) Excessive or prolonged distention will result in exhaustion or fatigue of the muscle coat of the muscle wall.

(4) In experiments on dogs, prolonged and intermittent distention of the intestine with air results in the production of a toxin of fatigue, which produces atony and dilatation.

(5) Antitoxins generated by fatigue toxins are obtained which neutralize the action of the fatigue toxins, which normally occurs during the period of rest.

(6) Toxins of fatigue are not dialyzable, and remain where formed. Rubbing, massage, or gentle exercise hastens the union of the antitoxin with the toxin, resulting in recovery from fatigue.

(7) The site of atony of hollow viscera is usually found in those organs used as reservoirs, such as stomach, colon, etc., because fatigue more readily occurs where the work is more apt to be in disproportionate excess to the rest period.

(8) The abdominal circulation is an important factor in relation to atony of the intestine. Venous blood predisposes to fatigue.

(9) The indications for treatment of atony are therefore: (*a*) The restoration of the chronic fatigue atony; (*b*) restoration of the congested vessels.

(10) Diagnosis, in connection with history and symptoms, can be made accurate by examination of feces observed during colonic lavage, and the reaction of the colon to distention.

(11) Drugs are useless as a cure; they aid certain symptoms, but ultimately increase the fatigue of the colon.

(12) Surgery does not correct the atony of the wall, though obstructions by tumors, etc., must be removed surgically.

(13) Treatment by general gymnastics is only indirectly helpful. They may strengthen the abdominal muscle, but do not increase peristalsis, or correct the atony of the intestinal wall.

(14) All methods of treatment usually resolve themselves into some form of mechanical treatment. In dietetics, coarse-grained food; cathartics producing excessive fluids. Drinking large quantities of water; gymnastics; exercises.

(15) Enemas of water are useful for the purpose of cleansing out the colon, as they excite peristalsis by distending colon, but do not correct the atony, on account of the resulting fatigue. They rather tend to create the enema habit, and increase the atony. Colonic lavage with high temperature, as described by the author, is useful.

(16) Injection of air directly is helpful, but in atonic colicky condition retention of air follows, and may result in increased fatigue or atony. This is, however, a useful method if the air is removed through the tube by pressure and massage upon the abdomen.

(17) By confining the air in the bag, and the rubber bag in the bowel, the degree of exercise by distention is under the direct control of the operator. Intermittent distention of the bags in the rectum or colon for a short period gives sufficient exercise and massage of the muscle wall to gradually restore the atony and fatigue of the muscle to a condition of normal peristalsis. If the colon is partly distended with air, then the rubber bag inserted into the rectum or sigmoid, with intermittent compression of the Politzer bag, causes vibration of the air in the entire colon to the cecum.

(18) The massage effect gives a valuable mode of treating various pathological conditions of the rectal mucosa—hemorrhoids, ulcers, proctitis, etc.

(19) It is useful in prolapse of the bowel.

(20) Associated pathological condition of the pelvic viscera; in certain diseases of the uterus and appendages, in female; and prostate, in male.

(21) The results have shown the restoration to be permanent.

## A CASE OF COMBINED EXTRAUTERINE AND INTRAUTERINE PREGNANCY.

By H. T. MILLER, M.D.,
SPRINGFIELD, OHIO.

Mrs. B——, apparent age 40 years; has had two children, daughters, who were born six and fourteen years ago. She has always enjoyed good health, except that in 1902 she was successfully operated on for strangulated hernia. Has always menstruated regularly until the fall of 1904, when there was a change in the menstruation, though it did not cease with the same regularity as in a normal pregnancy. The pain in the right side at times was quite noticeable. In the early part of November the abdomen in the region of the right iliac fossa became prominent. Though at times there were fainting attacks, there were never manifested symptoms of shock. In the latter part of January (1905) menstruation ceased entirely, only to commence again in the latter part of February. The flow was irregular and there were present all the symptoms of an impending abortion. About the middle of March the patient was attacked with an acute localized peritonitis in the right iliac region. From the history of the case, learned from her attending physicians, this attack must have been a severe one. During the attack of peritonitis the distention of the abdomen and the pain were so severe that a careful examination could not be tolerated. However, a tumor could be detected in the region of the right ovary. At this period the patient drifted into other and not scientific hands, and while she had seemingly recovered from acute symptoms she did not recover her former health; the abdomen remained prominent and she was always conscious of pain in the region of the right ovary.

While I had operated on the patient for the strangulated hernia, I did not see her for the present trouble until about the fourth day of May. I found, upon examination, a tumor about the size of an infant's head, occupying the region of the right iliac fossa, and the uterus, considerably enlarged, crowded into the left iliac fossa. From this history it was the opinion that there existed an extrauterine pregnancy dating from some time in the autumn. This being the conclusion, and an operation being deemed imperative, the patient was removed to the hospital. On the ninth of May the abdomen was opened, and a cystlike tumor, about the size of an infant's head, was found occupying the right iliac fossa, crowding the uterus over into the left iliac region. The tumor was composed of a membranous envelope, like the wall of an ovarian cyst. Some of the adhesions, which were quite numerous, were of recent origin. After freeing the tumor from its adhesions to the adjacent viscera it was found to possess a well-defined pedicle, composed of blood-vessels and the right Fallopian tube. The enlarged uterus excited a strong suspicion of there being an intrauterine pregnancy.

The walls of the tumor were about an eighth of an inch in thickness; at its lower pole was found a mass composed of tissue resembling in every particular the placenta; the center of this mass measured, roughly, about half an inch in thickness, while at its periphery it was lost in the walls of the tumor. In the pedicle was found an organized blood-clot protruding into the cavity of the sac. The cavity of the sac was distended with dark-colored blood, in which were floating masses somewhat resembling broken-down tissue—probably the fetus having undergone retrograde changes.

The patient left the operating-room in excellent condition, the time for the operation consuming twenty-five minutes. She did well until the morning of the second day after the operation, when I received word from the interne that the patient was having a serious flooding and was suffering severe pains. Before I could reach the hospital she had been delivered of a perfectly formed fetus of about four months. This coincided with the cessation of the menstruation in the latter part of January. The patient from now on made an uneventful recovery.

## ASTHENOPIA DUE TO LATENT HYPERPHORIA.

By G. DeWAYNE HALLETT, M.D.,
NEW YORK.
SURGEON TO THE N. Y. OPHTHALMIC HOSPITAL.

During the last several years, and by reason of the minute and exhaustive muscle testing which is applied to each asthenopic and refractive case examined, it has been my fortune to relieve distress in numerous instances, of which the following is a marked example.

Dr. F. B. E., a physician of this city, consulted me October 2, 1904, saying that he was referred by Dr. B., and that he despaired of relief through attention to his eyes, although he believed the fault to be there. Several oculists of wide reputation had had every opportunity, but failed to relieve his distress.

For over fifteen years he had suffered from fearful neuralgic headaches, which would incapacitate him for professional work for two or three days at a time. His only relief was obtained by rest in a darkened room and the ingestion of phenacetin and other coal-tar products, which he took frequently and in large quantities at all times in order to keep about at all. This drugging he felt was undermining his health, and he feared he would have to give up his practice. There was a severe pain in the back of the neck, specially bad in the morning if he had used his eyes during the previous evening or ridden much on the trolley cars. Another type of headache he had was a supraorbital neuralgia,

with lacrymation and blepharospasm. For about a year he had been wearing the following constant correction for astigmatism:

R. eye + 1.25 D. c. axis 180°.
L. eye + 1.25 D. c. axis 160°.

He was so nervous and irritable that he was almost in despair. No muscle fault was corrected, although it had been tested for on the suggestion of the patient.

My examination disclosed a need for:

R. eye + 1.50 D. c. axis 5°.
L. eye + 1.50 D. c. axis 150°.

Esophoria D. V. 2°; adduction 18°.
Exophoria N. V. 3°; abduction 5°.
*Left hyperphoria* ½°. Vision normal in each eye.

For trial purposes a prism ½° base down in the left eye was loaned him to wear over his old glasses until the next examination, nine days later, when he reported that the grab-front loaned him had been a comfort, and he had desired to keep them constantly on.

The test was the same as before, except that the *left hyperphoria* was ¾°. The following glass was prescribed:

R. eye + 1.50 D. c. axis 5°.
L. eye + 1.50 D. c. axis 150° *and prism ½° base down.*

October 17. While testing the new glasses to see if they were made according to prescription I again examined for the vertical fault, and found *left hyperphoria* 1-½°.

Further correction was loaned in a grab-front with ½° prism base up in the right eye.

October 24. Total *left hyperphoria* 1-¾°.

October 26. Total *left hyperphoria* 1-¾°. Loaned a grab-front with a ½° prism base up in the right eye and down in the left.

October 31. Total *left hyperphoria* 2°. The grab-front continued.

November 7. Total *left hyperphoria* 1-¾°, and the loaned grab-front continued.

November 14. Test as before, and I then changed his glasses to

R. eye + 1.50 D. c. axis 5° and prism 1° base up.
L. eye + 1.50 D. c. axis 150° and prism ½° base down.

During this time and following this the doctor was much more comfortable in every way, and could use his eyes in the evenings and at other times, and in ways not hitherto possible.

January 9, 1905. Lately has had an unsteady feeling in the eyes, and wonders if there is further vertical fault manifest. I found total *left hyperphoria* 2°, and loaned a grab-front ½° prism base down in the left eye.

January 23. Total *left hyperphoria* 2-¼°, and the glasses were changed to:

R. eye + 1.50 D. c. axis 5° with prism 1° base up.
L. eye + 1.50 D. c. axis 150° with prism 1° base down.

April 4. Total *left hyperphoria* 2-½°.

July 27. Total *left hyperphoria* 2-½°, and again the glasses were changed to:

R. eye + 1.50 D. c. axis 5° with prism 1-½° base up.
L. eye + 1.50 D. c. axis 150° with prism 1° base down.

These latter changes have each been made upon some slight return of the patient's old symptoms, each change giving relief.

Because cases of this kind are still strange and subject to doubt by many physicians every positive contribution has a certain value.

128 West Eighty-fifth Street.

---

**Climacteric Hemorrhage Due to Sclerosis of the Uterine Vessels.**—A. H. F. Barbour calls attention to the importance of carefully investigating uterine hemorrhage in patients at or near the menopause. He then discusses sclerosis of the uterine vessels, stating that the condition of the arteries in other parts of the body does not give information as to that of the uterine vessels; arteriosclerosis is found in them when it is not present elsewhere; the only treatment for this condition is hysterectomy. After studying the literature of the subject, the writer classes the cases that have come under his notice under three headings: Cases of arteriosclerosis, usually in women advanced in life, with hemorrhages and other marked naked-eye changes in the uterine wall, but no external bleeding of consequence; cases of uterine hemorrhage so severe as to call for hysterectomy, of which no pathological account is given, or in which nothing was found to account for the bleeding; cases of severe hemorrhage calling for hysterectomy, in which arteriosclerosis is the prominent lesion; while other minor changes in the mucosa are present, such as small-celled infiltration, there is no evidence of hemorrhage or infarction such as characterized the first group The writer cites a case of this nature which came under his care. Nineteen weeks before admission to the hospital this patient had a severe hemorrhage, which began on the day of her expected period, and which continued for sixteen weeks; hysterectomy was performed a week after admission. Arteriosclerosis was the prominent lesion found in the uterus.—*The Scottish Medical and Surgical Journal.*

**Scarlatiniform and Urticarial Eruptions After the Use of Diphtheria Antitoxin.**—J. Sabrazes and A. Delaunay tells us that the eruptions after the use of serums have been attributed to the precipitation, in the vessels, of the heterogeneous serum by the antibodies of the person receiving the injection, the result being the formation of minute thromboses in the skin, the origins of the eruption. This is supported by the precipitation occurring *in vitro* as a result of the contact of the serum of the patient with that of the injection. But in diphtheria it has been shown that there is no such precipitation, and that in seven out of nine cases there is no change in the skin. It is usually on the eighth to the twelfth day after the injection that the eruption occurs, exceptionally the thirteenth to the twenty-fifth day. The authors report a case of diphtheria, treated with serum, in which the eruption occurred very soon after the injection, and at each injection was renewed. The bacteriological examination showed diphtheria bacilli, streptococci, pneumococci, and staphylococci. The blood examination showed diphtheria bacilli, diplococci in the leucocytes, polynuclear leucocytes in great number, eosinophiles and lymphocytoidos. The scarlatiniform eruption appeared two hours after the injection of anti-diphtheritic serum. This early eruption could hardly be a serum eruption. After the second injection, on the following day, the eruption had extended and increased. The reaction of precipitation was tested *in vitro* without result. This case is opposed to the idea of precipitation of the serum introduced.—*Gazette Hebdomadaire des Sciences Médicales.*

MEDICAL RECORD.

New York, October 7, 1905.

## THE INFLUENCE OF MENSTRUATION ON THE ORGANISM.

THE pathological aspects of menstruation have been largely discussed in medical literature, but little attention has been given to what is denominated normal menstruation, and its effects on the physical and mental states of women. Those who have written on the subject are agreed that the menstrual act exerts a well-marked influence on the various bodily functions, and that this depends on chemical processes. A stimulus which proceeds periodically from the genital system, gives rise to an increased metabolism, which in turn manifests its effects on blood-pressure, temperature, muscular energy, etc. These superfluous metabolic products are then believed to find their way back to the genital system, there to be eliminated until the physiological balance is again restored.

A recent contribution to this question, and perhaps the most complete and extensive, has been published by Maria Tobler (*Monatsschrift für Geburtshilfe und Gynäkologie,* Vol. XXII, No. 1), in which are presented the results of investigations made in 1,020 German women, comprising all classes of society, and affording a fair average aspect of the female population in a civilized country. The investigation shows that menstruation among our modern women, contrary to what ought to be expected, is synonymous in most instances with a period of lowered vitality and impaired energy. This abnormal condition must not be, as it commonly is, regarded as essential and unavoidable. On the contrary, it is the result of a degeneration—a degeneration which can be referred on the one hand to an impaired constitution, on the other to an incorrect manner of living. The increased metabolic products already referred to, are not properly excreted or used up by the body, and exert a toxic effect on the latter. That this is not a normal condition is shown by the fact that a large number of women become the subjects of menstrual disturbances only after periods of prolonged freedom from trouble of this kind. Again, there are others who have never suffered, and some have even experienced during this time, a period of increased vital energy, as might, in theory at least, be expected during a time in which the system prepares for the possibility of forming and developing a new being.

Proper education of the young and growing girl in all that pertains to her menstrual function, is the only solution of the problem of how to increase the number (only 16 per cent., according to Dr. Tobler's investigation) of women free from untoward symptoms during this period. Such figures, and they can, without doubt, be duplicated in this country, are really appalling, when we consider how closely the sexual life is related to the community at large, for the welfare of the latter depends directly and indirectly on the ability of healthy mothers, not less than healthy fathers, to produce healthy offspring. The subject of venereal diseases receives a great deal of attention in the discussion of social questions, but it seems that some attention might, with profit, be directed to the subject here noted. A mother should see to it that her daughters are properly instructed in the significance of the menstrual period, and the important bearing on the latter of proper rules of living, of dress, and of hygiene. This would relieve much of what is now regarded as suffering to be borne without comment, and would tend to make one of woman's most important functions normal in more than name.

## LAMINECTOMY FOR THE PARAPLEGIA OF SPONDYLITIS.

IN 1889, Trendelenburg of Leipzig reported eight cases in which this operation had been done for the relief of paralysis due to deformity resulting from vertebral caries. Although the results were encouraging, but few surgeons have been tempted to resort to the procedure, only a small number of cases having been recorded in addition to those noted. Sultan has lately reported in the *Deutsche Zeitschrift für Chirurgie,* Vol. 78, Nos. 1 to 3, another series from the same clinic, and the data obtained from the entire number, fourteen, should prove of interest in judging the value of the procedure. Of Trendelenburg's patients, six were living at the time of the report, five being cured and one unimproved. Of the other six patients operated upon since then, three died at varying periods after operation without much improvement having taken place. A closer study of these cases shows that a laminectomy can be done most successfully when the vertebral caries is restricted, when the tuberculous process is quiescent, when the patient is not over twenty, and, finally, when the lesion in the cord is brought about by a stenosis of the bony canal. But even in the presence of epidural tuberculous processes, the removal of the arches will be followed by favorable results, because the cord is freed and better circulatory conditions are established. Where the lesion is high up in the cord, it would seem that the operation should be done early, as the prolonged decubitus, which cannot be avoided, greatly diminishes the patient's chances. The presence of vesical and rectal paralysis is considered an important factor in favor of operation, for laminectomy will obviate the complicating cystitis and ascending renal infection which usually sound the deathknell to these patients. It has happened, however, that a previously normal bladder has become paralyzed after operation, and although this condition is usually only temporary, the experience teaches caution in advising laminectomy when the bladder is not involved.

It is very important to possess some means by which one can recognize whether in any particular case, one is dealing with an irreparable lesion of the cord, or merely a simple compression. Unfortu-

nately, such a method has not yet been devised, and some patients will be subjected to operation needlessly. American surgeons have not expressed themselves very favorably with regard to the procedure, advising more conservative measures and reserving such radical treatment for cases where the latter have failed. It cannot be denied, however, that very brilliant results have been obtained in selected cases both here and abroad, and the large number of patients with spinal caries constantly met with in our clinics, renders any suggestion for bettering their condition, worthy of thought and attention.

## INSANITY IN ENGLAND.

As usual the report of the Commisisoners in Lunacy recently published in England, has excited great interest. Lunacy has increased in the past decade by leaps and bounds, although for some few years now the situation has shown improvement. In 1896 one in 319 of the English population was insane, while at the present time the proportion stands at one in 285. The most alarming increase was in the first five years of the decade. Naturally, the report contains some very instructive features.

To those who regard the deplorable increase of insanity in almost all civilized countries, as mainly due to the pressure of modern life, and especially to the struggle for existence in large cities, the report will present somewhat curious reading. The Commissioners state that "there is no apparent relationship between the density of population and the ratio of insanity." We commented, some few years ago, on a Scotch report on lunacy which drew attention to a similar state of affairs in the northern portion of Great Britain. It was then claimed that the monotony of country life was responsible for the greater prevalence of insanity in rural districts. However, this is, of course, by no means a full explanation. The fact must be borne in mind that the country districts are being continually drained of their best blood, to the corresponding benefit of the towns. Again, many which have been ruined in towns return to the country to end up in the insane asylums of their native districts. Nevertheless, it certainly seems an anomaly that the most sparsely populated counties of England should give the highest proportion of insane to the population.

The connection between drink and insanity is also dealt with in the report, and especial attention is drawn to alcoholic intemperance as one of the most fruitful causes of lunacy. During the five years, 1899-1903, intemperance was the cause assigned by medical superintendents of insane asylums in 22.7 per cent. of the male admissions, and 9.4 of the female; the rates for "private patients" being 16.7 males, 8.6 females, and for those in the pauper class 23.6 males and 9.6 females. As to whether the weak brain is the cause of drink or its sequence, the Commissioners are not decided. They state that "it should be borne in mind that intemperance is frequently as much an effect of brain weakness as a cause, and the intermingling of these renders it impossible to arrive at precise conclusions. In any case, it cannot be denied that alcohol is a brain poison, and it is, therefore, incumbent to show what part it plays in insanity."

The Commissioners with due caution and reservation, publish a provisional list of the causes, which they are of the opinion approximate to the truth. Of the moral causes we have: Domestic trouble, males 3.6 per cent., females 8.8 per cent.; adverse circumstances, males 5.6 per cent., females 3.5 per cent.; mental anxiety, worry, and overwork, males 5.5 per cent., females, 5.9 per cent.; religious excitement, males 1.1 per cent., females, 1.6 per cent.; love affairs, males 0.5 per cent., females 1.9 per cent.; fright and nervous shock, males 0.6 per cent., females 1.7 per cent. Among the physical causes are mentioned: Intemperance in drink, males 22.7 per cent., females 9.4 per cent.; sunstroke, males 1.3 per cent., females 0.1 per cent.; accident or injury, males 4.3 per cent., females 0.8 per cent.; fevers, males 1.2 per cent., females 0.8 per cent.; privation and starvation, males 0.9 per cent., females 0.9 per cent.; old age, males 7.1 per cent., females 8.5 per cent.; other bodily diseases or disorders, males 14.0 per cent., females 13.1 per cent. Hereditary influences were ascertained in males in 18.8 per cent., in females in 24.9 per cent. The cases in which the cause was unknown were, males 17.4 per cent., females 15.0 per cent.

With regard to the connection between drink and insanity, it is interesting to note that a great change has characterized the attitude of the medical profession in Great Britain towards the drink question of late years. Many, if not the majority of the most prominent medical men in the country, now hold that drink is most distinctly a brain poison, when used to excess, and that individuals in health are better without alcohol. Insanity would appear to be on the increase throughout the civilized world, and it would be instructive to ascertain whether statistics bearing on the matter in other countries than England show that lunacy is more prevalent in country districts than in cities.

## The Yellow Fever Germ.

It has been asserted several times, with a good deal of circumstantiality, in New Orleans despatches to the daily press, that the parasite of yellow fever has at last definitely been found by the Drs. Archinard and others working independently. The former have not yet published an account of their work, but four others, Drs. Pothier, Hume, Watson, and Couret, who have been studying the blood of yellow-fever subjects at the Isolation Hospital, have recorded the result of their investigations in the *Journal of the American Medical Association*. They regularly found in the blood certain cells of varying size and shape, some lying on (not within) the erythrocytes, but most of them entirely extracellular. According to their physical appearance and staining properties, these cells could be classified in four main groups. They were never found in the blood of healthy individuals, or those suffering from other diseases. So far as these investigations can be relied upon, and they appear to have been conducted with every care to eliminate the chance of error, it would seem that there are certain cells to be found in the blood in some, if not all, cases of yellow fever which are not always, if ever, present or visible in the blood in health, or in those suffering from other diseases. But it would be rash to conclude, without further proof, that such cells were parasitic, or that they had any pathogenic relation to yellow fever. They might have been degenerate forms, resulting from the cytolytic action of the yellow-fever germs, or they

might have been platelets; but that they were the germ itself is improbable. It is hardly possible that the many acute observers who have for years been searching the blood and the organs of yellow-fever subjects, and the bodies of stegomyia mosquitos that have sucked the blood of such subjects, in the hope of detecting the cause of the disease, should have failed to see cells varying in size from twice the diameter of a pneumococcus to one-fourth the diameter of a red blood corpuscle. The Marine Hospital Commission at Vera Cruz, of which, we believe, Dr. Pothier was one of the members, did, indeed, find cells of this size and appearance, but the claim that these were the specific organisms of yellow fever was very speedily disproved. If the pathogenic parasite of this disease is ever discovered, it will doubtless be found to be very small, if not of ultramicroscopic size, for it is almost certain that it is too small to be held back by a Berkefeld or Pasteur-Chamberland B filter.

### The Relation of Typhoid and Paratyphoid Infections.

The failure of the Widal test in certain cases presenting all the symptoms of a mild typhoid fever has led to the recognition of a new disease, called, for want of a better name, paratyphoid. This has been found to be associated with the presence in the body of a bacillus, morphologically distinct from Eberth's bacillus. The origin of the disease is as yet imperfectly understood, though it is probable that it is transmitted in the same way as typhoid fever, by means of contaminated water and food. Some experiments conducted by A. B. Smallman and reported in the *Journal of the Royal Army Medical Corps* for July, 1905, are suggestive in this relation. This investigator treated a number of guinea-pigs with living and dead typhoid bacilli, injecting pure cultures of the microorganisms into the abdominal cavity. About two hundred animals were subjected to the experiments. All died at varying periods following the injection. The bacilli cultivated from those animals after death, were in the majority of cases true typhoid bacilli; but in twenty-two cases in which living typhoid bacilli had been injected, the microorganisms found were of the type of the paratyphoid bacillus of Gärtner. They failed to stain with Gram's method, all showed a trace of indol, and they presented the morphological characteristics of paratyphoid organisms. The interesting question is whence they came. They were not found in the feces of the control guinea-pigs, but were present in the intestinal contents of the animals which had been inoculated with typhoid germs, and it would seem, therefore, possible that a transformation had been effected within the animal. It would be interesting to follow this clue to determine whether the paratyphoid bacillus in the lower animals is the analogue of Eberth's bacillus in man, and whether the latter may not be regularly transformed into the former in passing through the domestic animals, the dog or the cat for example, and so cause this infection in man. Whether an attack of paratyphoid fever confers immunity against genuine typhoid fever, is another point which it would be interesting and profitable to determine. If it does confer immunity, and if passage through one of the lower animals transforms the typhoid bacillus into the less virulent paratyphoid, there may here be a suggestion of protective inoculation against the more serious disease.

### The Health of New York.

The report of the Health Commissioner of New York for the first six months of the present year, which has just been submitted to the Mayor, makes an excellent showing, and bears gratifying testimony to the efficiency of the Board of Health of this town. From this report we learn that the death rate of the city has been reduced from 22.24, in the first six months of 1904, to 19.23 in the corresponding period of 1905. This is based upon an estimated population of 3,938,000, although the new census indicates a much larger population, which would give a corrected death rate of a little over 17, the lowest recorded since 1798. The total number of deaths was 37,969, as compared with 42,690 in the first half of last year. Dr. Darlington attributes much of this improvement in the mortality figures to the rigid watch which has been kept over the food supplies. Nearly 60,000 specimens of milk were examined and more than 19,000 quarts of adulterated milk were spilled, upward of $10,000 in fines being collected for violations of the law against milk adulteration. Over 4,000,000 pounds of fruit, 7,500,000 pounds of food and 1,000,000 pounds of meat and fish were condemned and destroyed. There was also a notable diminution in the number of cases of contagious diseases, only 17,456 being recorded, against 39,114 for the corresponding period of the previous year. For the week ending last Saturday —a week of nearly perfect weather conditions, it must be admitted—the death rate was only 15.75, as compared with 17.14 for the corresponding week of 1904. The figures would have been still lower had they been based on the new census. There may be and may have been certain favorable climatic or other factors contributing to the better health of the city, but the chief credit for the improved conditions must in all fairness be given to the Health Commissioner and his sanitary staff.

## News of the Week.

**The International Tuberculosis Congress** was opened in Paris on October 2, in the presence of President Loubet, the Cabinet Ministers, and the Ambassadors. Over 3,500 delegates were present. The American official delegation consisted of Dr. Henry Barton Jacobs of Baltimore, Dr. S. A. Knopf of New York, Dr. Lawrence F. Flick of Philadelphia, and Medical Inspector Henry G. Boyer, of the United States Navy. Many other Americans, delegates from various societies, were present. The opening address was delivered by Dr. Hérard of the French Academy of Medicine, who was chosen President of the congress. The report of Dr. Letulle, the secretary, said that thirty-three nations were represented in the Congress. An invitation has been extended through the American Ambassador to hold the next Congress in this country.

**Opening of the Columbia University Medical School.**—Dr. Samuel Lambert, dean of the faculty of the College of Physicians and Surgeons of Columbia University, in his opening address delivered on September 28, took as his theme "Some Present Fallacies in Medical Education." One of the practices he criticised was that of the students who, by substituting in hospitals before the examinations for internes are held, endeavor to find out the special points of each examiner in order that the information so secured may give them better chances at the examinations. Such "tips" he said were very rarely useful to the candidates. Another fallacy to which the speaker directed

attention was what he termed "trade unionism in medical education," by which the more able students were restrained from working to the full extent of their capacity in order that they might not seem to enjoy greater opportunities than their less intelligent and less well-prepared fellows. There has been a marked falling off in the size of the entering class at the medical school, owing to the increased requirements for admission, and the higher tutition fee, which is now $250. The first-year class in 1904 numbered 85, this year it has 79 members.

**Seaman Prize Awarded.**—At the fourteenth annual meeting of the Association of Military Surgeons of the United States, which opened in Detroit on September 27, Major Jefferson Randolph Kean, U. S. A., of Washington, D. C., was announced to be the winner of the Seaman prize for 1905. This is a prize of $500 offered for the best essay on "The Prevention of Disease in the Army and the Best Method of Accomplishing that Result." Major Kean's paper contained a plea for the reestablishment of the canteen at army posts, and he showed by statistics that since the abolishing of the canteen all kinds of diseases traceable to dissipation have increased among the soldiers of the regular army.

**Yellow Fever.**—Although the number of cases in New Orleans has passed the 3,000 mark, and the deaths are in the neighborhood of 400, the reports of the sanitarians continue to be very favorable. The Louisiana State Board of Health and Dr. White of the United States Marine Hospital Service have invited all the Louisiana towns to withdraw their quarantine against New Orleans, telling them that it is perfectly safe. All the public schools, except one, have opened. The remission in the outbreak is especially notable among the Italians, who at first were the greatest sufferers from the infection. In spite of these encouraging features, both Alabama and Texas have made their quarantines more strict, and a mounted force is patrolling the entire Alabama-Florida line. A few more cases are reported from Natchez, Vicksburg, and Pensacola. Reports on yellow fever from the Canal Zone have been unusually favorable of late. In the first two weeks of September there were but seven new cases and four deaths. Since September 15 there had been no new cases reported up to the first of this week. There is at present practically no yellow fever in Mexico, only a few scattered cases being reported by the Superior Board of Health, and the passage of September without an outbreak is regarded as a great victory for sanitary science. Cooler weather will soon set in, and then all danger will be over. A coal passer on the Panama Railroad's steamship *Havana*, was found sick of yellow fever on the arrival of the vessel here from Colon last week. He died after a few days' isolation at Swinburne Island.

**Death Rate in New York State.**—During August almost 12,000 deaths were recorded in New York State, a number about 1,000 in excess of the average during the past five years. The increase was largely due to an unusually large number of deaths in the rural towns, though 112 fatal cases of typhoid fever were reported from the maritime district, which includes New York City, and sixty-five fatal cases of whooping-cough from New York City and vicinity. The total number in the State was typhoid fever, 189—average for five years, 158; whooping-cough, 126—average, 80. Of the total number of deaths in the State, 1,090 were from tuberculosis, and 541 from pneumonia.

**Diphtheria at Annapolis.**—As a precaution against further spread of the epidemic of diphtheria at the U. S. Naval Academy, the authorities contemplate postponing the opening of the institution until October 15. Bancroft Hall, the original focus of the disease, has been vacated, and all midshipmen not affected, after fumigation of their belongings, have been removed to the United States Steamship *Hartford*, lying in the Severn River.

**Typhoid Fever at Norwich, N. Y.**—When the recent flood deluged this town, most of the wells became filled with impurities, but in spite of warnings from the authorities, the residents continued to use water from these sources. As a result, an epidemic of typhoid fever has broken out.

**Diphtheria at Oxford, N. Y.**—All of the lower schools in Oxford have been closed, owing to the prevalence of diphtheria. It is believed that the unhealthful conditions following the recent flood have been a factor in keeping up the infection.

**Iowa State Tuberculosis Association Organized.**—At Des Moines, Iowa, August 1, prominent representative medical men from throughout the State, together with a large number of laymen, met and organized the State Association for the Study and Prevention of Tuberculosis. The officers elected were as follows: *President*, ex-Governor Wm. Larrabee, Clermont; *First Vice-President*, Dr. R. E. Conniff, Sioux City; *Second Vice-President*, Dr. A. L. Urick, Des Moines; *Treasurer*, Prof. F. I. Herriott, Des Moines; *Secretary*, Dr. E. Luther Stevens, Des Moines. The committees appointed are composed of some thirty-five of the most prominent physicians, legislators, and educators in the State.

**The Killed and Wounded in the Japanese Fleets During the Russo-Japanese War.**—The following table of the killed and wounded in the Japanese navy during the late war was presented by Dr. S. Suzuki in his interesting paper, read before the Association of Military Surgeons, at the meeting in Detroit, September 28 (see page 597). The statistics embrace the period from the beginning of the war, to August 15, 1905. To the casualties here collected must be added those occurring during the burning and sinking of the *Mikasa*, a few weeks ago.

| Battles. | Killed | Wounded | Total | Termination of the Wounded | | | |
|---|---|---|---|---|---|---|---|
| | | | | Died | Recovered | Invalided | Under Treatment |
| Attack upon Port Arthur (February 9, 1904) | 3 | 69 | 72 | 6 | 59 | 3 | 1 |
| Battle of the Yellow Sea (August 10, 1904) | 65 | 161 | 226 | 6 | 133 | 17 | 5 |
| Battle off Ulsan Bay (August 14, 1904) | 36 | 96 | 132 | 10 | 80 | 3 | 3 |
| Naval Artillery Brigade at Port Arthur (From June 26 to last day of December.) | 30 | 313 | 343 | 27 | 258 | 20 | 2 |
| Battle in the Japan Sea (May 27-28, 1905) | 88 | 611 | 699 | 20 | 470 | ..... | 118 |
| Other Petty Battles and Accidents (1904-05). | 1,669 | 541 | 2,210 | 39 | 470 | 30 | 2 |
| Total | 1,891 | 1,791 | 3,682 | 11 | 1,470 | 73 | 131 |

**Dr. W. H. Wilder,** of Birmingham, Ala., has been elected president of the Tri-State Medical Association of Tennessee, Georgia, and Alabama, to succeed Dr. H. L. Appleton of Gadsden, Ala., who recently resigned.

**Dr. Jacobi at McGill.**—The opening address to the students of the medical faculty of McGill University was delivered on September 19, by Dr. Abraham Jacobi, of New York. In the evening he was the guest of honor at a banquet attended by the leading medical men of Montreal.

**Washington County (Vt.) Medical Association.**—At the annual meeting of this association, held in Barre, on September 12, the following officers were elected: *President*, Dr. Wm. Lindsay of Montpelier; *Vice-President*, Dr. C. F. Camp of Barre; *Secretary*, Dr. O. G. Stickney of Barre; *Treasurer*, Dr. C. E. Chandler of Montpelier.

**New President of the British Medical Association.**—At a meeting of the Toronto branch of the British Medical Association recently held, Dr. R. A. Reeve, of that city, was elected president of the association in anticipation of the projected meeting of the British Medical Association to be held in Toronto next year. This is in accordance with the custom of having the presiding officer for each annual meeting chosen from among the medical men of the city in which the association convenes.

**Medical Control of Marriages.**—The homeopathic practitioners of Colorado, are endeavoring through their State society to have the Colorado legislature at its next meeting enact a law restricting marriage to the physically fit. The proposed bill provides that all applicants for marriage licenses, both men and women, must submit to a physical examination, and if any couple is unfit to wed because one or both has some incurable disease, or is undeveloped, then a license shall be denied.

**Increasing Sale of Opium in New York.**—It is stated that there has been a great increase in the sale of opium for illegal purposes of late. Many dangerous Chinamen who left the East side when the strife between the rival tongs became too hot are now located in "Poison Row," on Seventh Avenue between Twenty-ninth and Forty-second streets, and in other parts of the Tenderloin, selling opium in large quantities. It is alleged that this violation of the law is openly carried on with the connivance of the precinct detectives.

**The Cholera.**—It is officially announced that fifty cases of cholera, with twenty-eight deaths have occurred in Poland, between September 20 and September 27. In Germany, the authorities appear to have thorough control of the situation, and the cases are so few in number that regular reports of new cases and deaths are no longer made. The water of the River Spree has been declared contaminated and residents along its banks have been warned not to use the water.

**The Brooklyn Water Supply.**—In a statement relative to the occurrence of colon bacilli in the Brooklyn water supply, given to the public press by Health Commissioner Darlington, he again urges the necessity for establishing sand filter beds for the city, and advises the residents of Brooklyn to use no water that has not been boiled.

**A Vermont Sanatorium for Consumptives.**—Senator Proctor, in a letter to Dr. W. N. Bryan, of Ludlow, Secretary of the Vermont State Tuberculosis Commission, announces that he will purchase a site and erect a sanatorium at a cost of about $50,000 for treatment in incipient cases of tuberculosis. In addition, the Senator promises an endowment fund of $100,000 for the institution, which it is intended shall accommodate from twenty-five to thirty patients. The site has not been selected but will soon be announced.

**Turning Condemned Criminals to Use.**—A correspondent of the *Lancet* suggests that condemned murderers be given the option of submitting themselves to some simple pathological experiment as an alternative to being hanged. The writer urges that a life which is forfeited by the State should be used for some good end, instead of being wasted. He says that both tuberculosis and cancer offer problems that could easily be settled in this way with great resulting benefit to society at large, and expresses the belief that most criminals would choose the chance of life afforded by such experiments. The proposal is not new, and, though it has certain features to commend it, is hardly in accord with modern principles of humanitarianism.

**The Quatercentenary of Sir Thomas Browne.**—Sir Thomas Browne, the author of "Religio Medici," was born on October 19, 1605, and the quatercentenary will be celebrated at Norwich on the same date this year. The memorial statue of Sir Thomas Browne, erected in the Market Place, will be unveiled at 12.30 P. M. by Lord Avebury, F.R.S.; afterwards a luncheon will be held at the Blackfriars Hall. At 8.30 P. M. there will be a service in memory of Sir Thomas Browne in the Church of St. Peter Mancroft, Norwich, near which he lived for many years, and in which he worshiped, and lies buried; the sermon will be preached by the Right Rev. Bishop Mitchinson, Master of Pembroke College, Oxford, of which college Sir Thomas Browne was a member. —*British Medical Journal.*

**Report of the Ray Brook Hospital.**—The trustees of the New York State Hospital for Incipient Pulmonary Tuberculosis in the Adirondacks, have issued their report for the first year. Two hundred and seven patients were admitted during the year, more than half of whom were incipients. There were no deaths. Of the 105 patients discharged, fifty-two were apparently cured.

**Suicide in Maine.**—According to the statistics compiled by Dr. A. N. Young, Registrar of Vital Statistics, suicide is increasing in Maine. Seventy-seven persons took their own lives this year, as compared with fifty-nine last year. Of this number sixty were males and seventeen females. Of the males twenty-one were farmers. The youngest suicide was a girl of seventeen, and the oldest a man of eighty-five. The largest number of suicides in any month was nine, in May. The rate for the State per 10,000 of population was 1.11 per cent. Twenty-one persons committed suicide by hanging, 21 by shooting, 15 by drowning, 13 by poisoning, 4 by cutting throat, 2 by jumping from high places and 1 by asphyxiation. The largest number of suicides were between the ages of fifty and sixty years, and the smallest number between the ages of ten and twenty years

**Work of the Strauss Milk Depots.**—The Nathan Strauss pasteurized milk stations in the parks and on the recreation piers have been closed until next year, but the stations at 151 Avenue C, 241 East Fifty-ninth street, 441 West Thirty-third street, 169 West Houston street, 301 East One Hundred and Eleventh street, and 45 Monroe street, remain open throughout the year. The de-

mands on the laboratory were so great during this summer that it was taxed to the utmost, and the necessity for increased facilities is urgent. The number of bottles of milk dispensed in the year was 2,668,397, as against 2,149,194 for the previous year. In addition, 807,070 glasses of milk were sold at a cent a glass. The Health Department statistics show the death rate among children under five years of age in 1890 and 1891, prior to the use of pasteurized milk among the poor, was 96 in 1,000, while for the year 1904 the rate was 63 in 1,000.

**Diphtheria in Boston.**—The week ending September 23 shows a gratifying decrease in the morbidity from this disease. For the corresponding week of last year forty-one cases were reported, but this year the number is only twenty-two, with two deaths.

**California State Board of Dental Examiners.**—The commission appointed by the Governor to investigate the charges against the California State Board of Dental Examiners, after holding meetings for two weeks and examining ninety witnesses, has reported in effect that there was no urgent necessity for the investigation. They found that several members of the board were injudicious in their handling of the question papers, as well as in their criticism of their fellows, but there was no intentional wrongdoing and the financial accounts were correct. The entire difficulty arose from professional jealousies. The report intimated, however, that the usefulness of at least two members of the board was at an end.

**A Knights Templar Asylum.**—The Knights Templars of San Francisco, at a recent banquet, subscribed $65,000 for the building of an asylum, the estimated cost of which is about twice the amount thus raised. The work of construction will begin immediately.

**A Study of the Diseases of Insect Pests.**—The department of agriculture of the University of California has been engaged for several years in the study of the diseases of the insects that destroy various crops in this and other states, and in several instances have met with great success. Since July Prof. Clarke, assistant entomologist, had been studying a bacterial disease that completely exterminated the grasshoppers at Los Banos. The disease was of unknown origin and in the course of a month destroyed a countless army of the insects, after they had entirely devoured the alfalfa crop.

**Dr. Hermann E. Hasse** has recently tendered his resignation as chief surgeon to the hospital of the soldiers' home at Sawtelle, near Los Angeles. Dr. Hasse received his degree at the University of Wurzburg in 1861, then came to America and served in the civil war. He was instrumental in establishing the soldiers' hospital eighteen years ago and has had charge of it until the present time. He is now seventy years of age, and the desire for rest is the cause of his resignation.

**Vaccination Tetanus.**—A third death within a year from tetanus following vaccination has recently occurred at Oakland, California. In this case, however, five weeks had elapsed before infection of the wound became apparent and it is quite unlikely that the virus had become contaminated. Unfortunately the child was the son of an anti-vaccinationist who had consented to the vaccination after having kept his child out of the public schools for a year or more to avoid it.

**A French Consumptive Sanatorium.**—Near Lille, in the heart of the "Black Country" of France, we hear from *The Hospital*, there has lately been established a sanatorium for tuberculosis which differs in several respects from any established in this country. The sanatorium is really a village, and comprises a building for unmarried men, another for unmarried women and twenty-four "villas," which form forty-eight houses for families. The rules of the colony demand that each patient shall take the rest and fresh air cure for six hours a day, but the time may be divided at will so that nothing more than a frequent lounge is consciously demanded of him. In fact, this French village for consumptives seems intended to produce the maximum of benefit with the minimum of restraint.

**Suit to Retain a Medical License.**—The Supreme Court of California has granted a writ returnable in October, calling for a reconsideration of the charges against a female cancer doctor in consequence of which the State Board of Medical Examiners revoked her license to practice, and requiring a reissue of the license if the charges prove to have been false as the accused physician claims they were.

**To Study American Methods.**—A number of medical men and others, composing the sub-committee of the Royal Commission on the Care and Control of the Insane, sailed from Liverpool for New York on Saturday last to investigate American methods of treating the insane

**Obituary Notes.**—Dr. A. J. VIDAL of Gainesville, Fla., died on September 22, after a long illness. He was a Confederate veteran, and was wounded several times during the war. He was graduated from the Medical College of the State of South Carolina, in 1869.

Dr. E. D. STEEL of Monkato, Minn., died on September 21, at the age of forty-three years. He was president of the Blue Earth County Medical Society, and for many years was secretary of the Minnesota Valley Medical Society. He was graduated from the University of Minnesota, in 1889.

Dr. C. S. BOYNTON of Indianapolis died on September 23, at the age of seventy-two years. He was graduated from the University of Buffalo, in 1857, and practised in Elizabethtown, Ind., until 1871, when he removed to Indianapolis. He was a veteran of the Civil War.

Dr. GEORGE H. RICKER of Minneapolis died suddenly of heart failure on September 23, at the age of fifty-one years. He was born in Bangor, Me., but grew up in Minneapolis, and was graduated from the Habnemann Medical College of Philadelphia in 1878. He was made professor of surgery in the Minnesota State College of Homeopathy in 1888, and retained the position until his death. In 1903 he was appointed city physician.

Dr. A. A. DREHER of Cleveland died on September 18, at the age of forty-six years. He received his diploma from the Western Reserve Medical College.

Dr. F. A. SMITH of Springfield, Mass., died on September 26, at Belbort, Texas, while on his way to El Paso, where he was to spend the winter. He suffered from tuberculosis during the past five years, and traveled from place to place, in hope of finding a suitable climate. He was fifty years of age, and was graduated from the Harvard Medical School.

Captain G. C. M. GODFREY, Assistant Surgeon United States Army, died suddenly at Fort McPherson, Ga., on September 23. He was a son of Col. Edward S. Godfrey, Ninth Cavalry, and was born in Ohio, October 12, 1870. He was appointed

an assistant surgeon in May, 1893, and received the rank of captain in October, 1898. Captain Godfrey was a graduate of the College of Physicians and Surgeons of Baltimore.

Dr. Thomas Milton Todd, a native of Ohio Co., W. Va., died on September 15, at the age of sixty-six, in East Auburn, Cal. He received his degree from the Miami Medical College, Cincinnati, in 1869, and has resided in California since 1876. A brother of the deceased, Dr. J. Hamilton Todd, resides in Oakland.

## Obituary.

### HENRY DORWIN DIDAMA, M.D., LL.D.,

SYRACUSE, N. Y.

Dr. Henry D. Didama, one of the most widely known and respected physicians of western New York, died on Wednesday of this week, at the age of eighty-two years. His death followed a fracture of the hip received in a fall several months ago. He was born at Perryville, Madison County, N. Y., June 17, 1823. His father was at one time a prominent practitioner in New Jersey. He was a graduate of the Albany Medical College in 1846. He was for more than two decades one of the faculty of the School of Medicine of Syracuse University, and was dean of the faculty up to June of the present year, when he was made dean emeritus. Dr. Didama was a member of the Syracuse Academy of Medicine, of the American Academy of Medicine, of the American Medical Association, of the American Medical Temperance Association, and of the New York State Medical Association.

Dr. Didama was a founder of the New York State Medical Association, and for many years one of its most enthusiastic members; he served for a term as president of the association. He was a strong advocate of abstinence from the use of alcohol and never prescribed this drug in his practice.

## Correspondence.

### THE COUNTRY DOCTOR AND THE SURGEON.

To the Editor of the Medical Record:

Sir: Your editorial in the issue of the Medical Record for September 23 on Dr. B. R. Riley's article of recent date in the *Medical News* as to the mutual relations between the city and country doctor is timely and of interest to both the country and the city practitioner. May I, as a city practitioner and teacher in one of the post-graduate medical schools, be permitted to say a few words on this subject?

While I agree with Dr. Riley in the main in what he says concerning the relations of the city and country doctor, I am inclined to believe that he is mistaken in the conclusion that the present tendency of specialism in medicine is to weaken the country practitioner, particularly in a surgical way. Now, my own experience as a teacher in the city, and observation in the small country towns in the middle West, which I visit every summer, lead me to disagree with his view of the subject. Indeed, since the founding of the post graduate medical schools in this city in 1882, and later in other cities—Chicago, Philadelphia, etc.—and hospital clinics have been opened to the country practitioner, he has not been weakened, but, on the contrary, immeasurably strengthened, and especially along surgical lines. Twenty years back major surgical operations in small towns were almost unheard of; but to-day, even in country villages, the major surgical operations are performed, and successfully. In the larger towns of 20,000 to 50,000 inhabitants usually a general hospital is to be found wherein not only major surgery is done, but original surgical technique is developed—witness the Mayos in the West. And even in the country villages one is surprised at the number of "private" hospitals, wherein there may be only two, four, six, or, exceptionally, as many as a dozen beds; capital operations are performed, and almost, if not quite, with the success following those done in the metropolitan centers; the strong constitution of the patient and fresh air counterbalancing, if you please, to a great extent the superior technique to be had in the city hospital.

The following, an actual occurrence, is an example of what country practitioners may be called upon to do at a short notice: A call into the country of about six miles from the small town at twelve o'clock at night, to an old gentleman, seventy-one years of age, suffering with strangulated hernia. Operation decided upon immediately. Assistants, two old ladies, to hold oil lamps, and a fellow neighboring practitioner to give chloroform. Operation with resultant complete cure, and patient discharged one week later.

It happens, too, nowadays, that trained nurses may be had from neighboring cities to take care of surgical cases, which was not possible twenty years ago. Altogether, the country practitioner finds himself much better prepared to-day to take care of his surgical cases than formerly; and, what is more to the point, he is taking care of a great many cases that he formerly sent to his city brother. Specialism has not weakened him, in my opinion, but, on the contrary, strengthened him. We might pause to ask what has been the factor in bringing about this change for the better—that is, the establishing of private hospitals in smaller towns, and public hospitals in small cities? Manifestly the founding of these hospitals is due to the fact that more men have been qualified to practice the art of surgery, and the one factor more than any other to bring this about has been clinical instruction at the post-graduate schools and at hospital clinics. Mind you, we are not among those who believe in making a man a specialist after six weeks' instruction. The successful men who have gone out from these schools are those who in the beginning took out a six months' or even a year's post-graduate medical course, and who later, as well suggested by Dr. Riley in his paper, returned to the city every two or three years for further instruction. In this way they are kept abreast of the times, and the patient, even in distant parts, is taken care of—thanks to clinical instruction.

A. Edward Davis, M.D.

New York.

### OUR LONDON LETTER.

(From Our Special Correspondent.)

VACATION CLOSING—AMALGAMATION OF SOCIETIES—REPORT ON INSANITY—REPORT OF MEDICAL OFFICER OF THE LOCAL GOVERNMENT BOARD—SCOTCH CROFTERS—DEATH IN ASYLUM—CAMPHOR POISONING—VEGETARIANS.

London, September 15, 1905.

The long vacation is drawing to its close, and a number of teachers have already returned from their holidays to prepare for the coming session. The question of amalgamation of the medical societies will then come up once more, and many are sanguine that this time union will be effected. There are some 7,000 members of about twenty societies whose interests have to be considered. I hear that the report of the committee appointed is practically completed, and will probably be discussed in October. This report is in favor of amalgamation, or perhaps the creation from the old institutions of a new body under the name of Royal Society of Medicine, or, better still, as I suggested last year, Royal Academy of Medicine, to bring it into line with other similar bodies, continental and American. The Irish societies amalgamated into an academy with several sections some years ago, and surely the English should be able to reconcile their several interests. It is said the committee suggests sixteen sections of the new academy. I suppose as the Medico-Chi., our previous society, is royal, the new one may have the title. The Medical Society of London will most likely first consider the project, and its decision will greatly influence the younger societies.

The fifty-ninth annual report of the Commissioners in Lunacy appeared this week as a Blue Book dealing with a great number of things connected with asylums, such as the annual movement of our asylum population, the proportion of first attacks, the causes of insanity, and its forms. The duly certified insane under care on January 1 last in England and Wales numbered 119,829, being 2,630 in excess of the number on the same day in 1904. This increase may be compared with 3,235 for 1903, 3,251 for 1902, and 2,769 for 1901. In relation to the estimated population, the insane stood on January 1 as 1 to 285. The increase of population in the last nine years is put at 10.8 per cent.; that of the insane has been 24.2 per cent

It is pointed out that in the present state of knowledge all that can be done to determine the cause of an attack is to record as carefully as possible the antecedents which seem to stand in relation to it. This is the more difficult as several antecedents may be concerned, while in other cases the responsible agent may be also the cause of the impaired resistance of the brain. Special attention is directed to alcoholic intemperance, which appears as the assigned cause in 22.7 per cent. of the male admissions and 9.4 per cent. of female. These figures are from the returns of superintendents of institutions for the five years 1899-1903, and in reference to them the commissioners remark that intemperance is often "as much an effect of brain weakness as a cause, and the intermingling of these renders it impossible to arrive at precise conclusions. In any case, it cannot be denied that alcohol is a brain poison."

Density of population does not seem to imply a high rate of insanity. In fact, some of the sparsely populated counties give the highest proportion of insane to their respective population. During last year the statistics show a greater increase in rural districts than in towns. A good deal of speculation is already rife as to the cause of this. Medical men are unable to account for it, and the newspapers are inclined to discuss it. The suggestion that it is a "freak of nature" should come only from those who possess a supernatural faith in statistics and their ability to interpret them. It is far more probable that many persons now registered as lunatics have previously been passed by as eccentrics, or half-witted, or daft. Heredity again is the favorite explanation of many, and they say that in villages this is reinforced by intermarriages more than in towns. Some of them go so far as to say that in-and-in breeding is itself a cause of both physical and mental degeneration, though their view does not gain any support from the experience of animal breeders. The struggle for existence and the survival of the fittest are phrases quoted by others as a complete explanation. But others, again, declare it is the wear and tear of our strenuous life with its constant excitement—though surely this should affect the cities more than the villages. Poverty and vice are common to both classes. In fine, we may perhaps do well to admit that we have no satisfactory explanation to offer.

The report of the Local Government Board's medical officer for 1903-4 appeared this week, and is as full and important as usual, as the reports of the inspectors issued during the year are included and the series of appendices on various scientific investigations made for the Board are continued. The chief medical officer, Mr. W. H. Power, draws attention to the failure of the Spenrigmoor (Durham) local authorities. This is by no means the first time that such a complaint has been made, and that body seems to ignore its responsibilities, as it has long ignored the representations of its own medical officer of health, even when they were made at the instigation of the Durham County Council. Two other local boards are pilloried in this blue book. One of them is Whitehaven. You will remember that the outbreak of typhoid there in 1901 led to a special inspection by Dr. Bulstrode, who reported on the urgent need of certain sanitary reforms. A subsequent report by Dr. Farrar shows that the evils found by Dr. Bulstrode still remain. These examples seem to show some authority is needed which should compel such bodies to do their duty. We cannot be always appealing to the legislature to enforce its edicts, and either the Government Board or the County Council must be armed with more powers. When the Government Board has investigated fully and the local body will not follow its advice, it might well exert compulsion, especially in the presence of epidemic diseases. Another subject on which some authorities display neglect and even opposition—vaccination—comes in for notice in this blue book. Mr. Power refers to the report of Dr. Bruce Low on the results obtained in Germany, of which the conclusion is that "it is not possible to deny that had this country given heed, as Germany has done, to the lessons of the smallpox pandemic of 1870-3, London might have been saved the enormous cost which she has since been called on to bear in removal and maintenance of her smallpox hospitals beyond the metropolis."

Among other investigators one cannot pass by Dr. Klein's further report on plague bacillus. He confirms and extends his previous conclusions as to two types of the microbe. The human type is very virulent to rodents, but the rat type is less so. This latter soon loses its virulence in subcultures, but this is not the case with the human type. Dr. Klein found, however, that it is possible to diminish the virulence of the human type so as to make it almost the same as that of the rat. This he accomplished by inoculating rats with highly potent plague material after they had been protected by subcutaneous injections of Haffkine's preventive.

In connection with this interesting research I must mention a report by Drs. Haldane and Wade on the Clayton plan of killing rats on shipboard. On the whole, they favor the method for destroying the rats before discharging cargo if it can be carried out at a reasonable cost. There are, however, several difficulties, and further investigation will be made.

A report to the Scotch Local Government Board issued this week discloses a disgracefully unsanitary condition of some of the Crofters' cottages. Dr. Dittmar, medical inspector, and Mr. Millar, general inspector under the Public Health Act, found among the poorest inhabitants an appalling state of squalor; cottages built of loose stones, with turf roofs, with scarcely any partitions between the byre and sleeping room; drainage channels in front often choked, and other dangerous conditions, and yet in these squalid surroundings healthy-looking young men and women. But they were not surprised to hear that whole households had been carried off by phthisis. Though the elder boys and girls looked well, the young children under five were "miserable, puny, and anemic-looking things."

A strange death in a lunatic asylum seems to call for more careful inquiry than the coroner's inquest supplied. The man was admitted on Saturday, August 19, when the assistant medical officer said he was free from marks of violence. On that day week the same doctor was called to him, and found him in the padded room, dead, his body covered with bruises, and ten of his ribs had been fractured. No explanation was obtained, and it was suggested he had fallen over a hair mattress in the padded room. The foreman of the jury naturally enough declared that it was childish to suppose such injuries could have been inflicted in that way, and another medical man said they were due to direct violence. The verdict ascribed the death to shock and fractured ribs, but how caused there was not sufficient evidence to show.

Another inquest resulted in a verdict of death from "camphor poisoning, but there is no evidence to show how the poison was taken or administered." It appeared that the man left his business, and was found dead ten minutes later. There was no suggestion as to suicide, no trace of camphor was found outside the body, and it was not possible to determine how it got into the stomach.

Some of the Borough Councils are getting up an agitation as to what becomes of the calves used for preparing lymph for vaccination. The Government Board has declined to assist in an inquiry which has been asked for, and so some local authorities are charging it with having permitted the sale for food contrary to the act, or else of unwillingness to allay public alarm.

Vegetarians are generally enthusiastic, and every now and then put forth fresh statements of their experience and expectations. The Hon. R. Russell has just published a volume in which occur assertions which seem to require a grain of salt to digest them. I can scarcely credit that women and children "gloat over the horrible sights of butchery," or are corrupted by reading directions in cookery books to chop up sheep's brains with parsley. It is true that Porphyry attributed many diseases to eating meat, and Richardson thought the use of tea—or, rather, its abuse—was a source of much misery to poor women. John Wesley, too, thought he got rid of unsteadiness in his hands, which he fancied were paralytic, by leaving off tea. But these things hardly justify the conclusions of Mr. Russell that our national degeneration is due only to diet, and that we must give up meat, tea, coffee, alcohol, etc., and content ourselves with porridge, toast, fruits, and vegetables, with perhaps milk, if we would arrest our progress to decay.

---

## Progress of Medical Science.

*New York Medical Journal, September 30, 1905*

**Operations for Ingrowing Toe-nail and Hallux Valgus.**—V. Kenerson refers to the customary household procedures for the relief of these conditions. He then describes one or two operations which have proven of service in his hands. Careful disinfection of the entire region of the toes is first practised for several days. Details are given of the method of injecting cocaine into the affected toe. A sharp-pointed, narrow-bladed scalpel is then passed, beginning well back of where the matrix and the root of the nail can be felt underneath the skin. The point of the knife is placed with the blade vertical to the plane of the foot, and the knife is plunged through the top of the toe right down through to the sole, being kept close to the nail, but not cutting the latter at all. The incision is made to the tip of the toe, and the piece of flesh thus loosened is removed. The raw surface left will heal in three or four weeks, and as it does so the natural contraction

will draw the edge of the flesh still further away from the nail. In another procedure the knife should be thrust down through the toe close to the bone, being held vertically to the plane of the foot, and when it has appeared through to the plantar surface of the toe, the incision is made along close to the pharyngeal bone and the edge of the nail that is vertical to the plane of the foot (usually about one-quarter), is cut off. The knife is swept directly through to the tip of the toe. This cuts from the side of the latter a slice approximately three-eighths of an inch thick, containing the skin and surrounding tissue and about one-quarter of the nail, but attached at the proximal end of the flap. This is laid right back on the side of the toe, and all of the nail and the matrix and all of the inflamed and diseased parts should be carefully trimmed away with a pair of scissors curved on the flat. Then the flap is sutured back in place with black silk. In a week the patient is generally able to resume his shoe.

**Sodium Glycocholate in Diseases of the Liver.**—According to H. Richardson this remedy is indicated in all diseases in which toxemia is a factor, and with a few exceptions in all cases of hepatic insufficiency. In many cases of malnutrition from want of proper absorption of fats, it will materially aid in building up a patient. Above all, it is indicated in hepatic colic and gallstones; in the former it is almost a specific, and, in chronic constipation combined with the purgative habit, it is of great value. The dosage is about 5 grains three times a day, though as much as 15 grains may be given without producing nausea. As the action of the drug is cumulative, owing to its resorption from the intestine, it is not necessary to keep up the full dose for any great length of time. In hepatic colic it is advisable to continue the administration for some months. The patient should take about four drachms a month, regularly, as a prophylactic. In all forms of hepatic insufficiency sodium glycocholate is indicated as a hepatic stimulant in conjunction with other treatment. In arterial sclerosis, in conjunction with the administration of the inorganic salts of the plasma in their proper percentage, it dissolves the cholesterin in the atheromatous deposits, while the salts mentioned tend to dissolve and to prevent the deposit of the calcium salts. In diabetes, when increased absorption of fats is necessary to replace loss of carbohydrate, and in tuberculosis, in which fat hunger is a pronounced symptom, the remedy of often of service.

*Medical News, September 30, 1905.*

**The Serum Diagnosis of Tuberculosis.**—The conclusions presented by H M. Kinghorn are as follows: (1) In far advanced cases with very extensive or virulent lesions the serum reaction is generally absent. (2) The reaction seems to appear most often with the most favorable cases. (3) A certain number of favorable cases with well-marked signs of disease fail to show any agglutination. (4) Nine out of 12 persons in robust health reacted to the test. Six of the 9 were in close contact with tuberculous patients. (5) In the tuberculous cases the average agglutination power was 1 to 10, in the healthy cases the average agglutinating power was 1 to 23. (6) Up to the present time the author does not feel justified in relying on the serum test as being a sure and reliable one for the presence or absence of clinical tuberculosis.

**The Vitality of Tubercle Bacilli in Sputum.**—From an elaborate series of experiments D. C. Twichell presents the following results: Tubercle bacilli in sputum in paraffined bottles placed in a dark, moist box, were alive and produced a tuberculous lesion in a guinea-pig at the end of 170 days. No tuberculous lesion was produced after 188 days. With the sputum in paraffined bottles, placed in a dark closet, a lesion resulted after 160 days, but not after 188 days. With the sputum in bottles stoppered with cotton, placed in a dark, moist box, a lesion resulted after 157 days, but not after 172 days. With the sputum in paraffined bottles placed in the diffuse light of an ordinary room, a lesion resulted after 124 days, but not after 175 days. With the sputum in ice a lesion resulted after 102 days, but not after 153 days. With the sputum in sand, in a moist, light place, a lesion resulted after 123 days, but not after 148 days. With the sputum in bottles stoppered with cotton in a dark closet, a lesion resulted after 100 days, but not after 141 days. With the sputum in open bottles, placed out of doors in the winter months, a lesion resulted after 110 days, but not after 132 days. With the sputum in a handkerchief, a lesion resulted after 70 days, but not after 110 days. With the sputum in a woolen blanket, a lesion resulted after 70 days, but not after 110 days. With the sputum on wood, a lesion resulted after 70 days, but not after 110 days. With the sputum in paraffined bottles, in the thermostat, a lesion resulted after 33 days, but not after 100 days. With the sputum on carpet, a lesion resulted after 30 days, but not after 70 days. With the sputum in sand, in a dry, light place, a lesion resulted after 30 days, but not after 70 days. With the sputum exposed to direct sun rays, a lesion resulted after one hour, but not after seven hours. It appears that the conditions most conducive to the prolonged life of the tubercle bacillus in sputum are darkness and moisture.

**Studies of Immunity in Tuberculosis; the Properties of the Serum of Immunized Rabbits.**—From the paper of E. R. Baldwin, H. M Kinghorn, and A. H. Allen certain facts are herewith presented relative to the phagocytosis of tubercle bacilli as influenced by the sera of immunized and control rabbits before and after inoculation. They found that no marked difference was noted between vaccinated and control sera, before and immediately after the virulent inoculation. Both sets of animals inoculated showed considerable individual variations from day to day, but all were weaker on the first two days following infection. The vaccinated sera were usually below the controls in opsonic (devouring or consuming) power from the beginning, and two pairs of animals which had shown the greatest variation, when bled to death, revealed the typical differences between the lungs of the vaccinated and the controls to a marked degree. One pair was killed on the sixteenth and one pair on the twentieth day. If the intense reactive infiltration be regarded as an active phagocytosis, which it appears in part to be, the lower opsonic power of the sera may be accounted for by its exhaustion, though evolved in excess of that in the controls. Finally, the authors state that the intense reaction seen in vaccinated rabbits was observed only in the lungs, where doubtless most of the bacilli lodge; and in a few animals the reaction was evidently followed by such lowered resistance that instead of absorption large caseous areas developed, much more extensively than in the controls. Thus one cannot say that the method of vaccination always succeeds at last in destroying the bacilli and removing the tubercles, though it must be remembered that these inoculations are extremely severe conditions for animals to withstand. Moreover, the absorption of foci in the controls was occasionally observed to nearly the same degree, and the presumption is that the mechanism is the same, but delayed and less active in unvaccinated animals.

**Two Experiments in Artificial Immunity Against Tuberculosis.**—E. L. Trudeau describes his experiments suggested by the previous demonstration of the fact that a human culture of bacilli lost by prolonged cultivation its virulence for guinea pigs, and that its injection gave to these animals a relative degree of immunity. The main object was to determine if the immunity was a result of the struggle between the living bacillus and the cell or cells, the factor of immunity resident in the chemical properties of the bacillus whether living or dead. The details of the experiments cannot be enumerated here. Suffice it to say that in a general way they showed: (1) that dead tubercle bacilli increase, though to a very slight degree, the animal's resistance to subsequent inoculation; (2) that the living attenuated bacillus gives a stronger degree of immunity than the same bacillus killed by heat; (3) that the degree of attenuation of the bacillus used as vaccine bears a distinct relation to the degree of protection it affords in guinea pigs to subsequent inoculation with virulent human cultures. That a culture still capable of producing a very small amount of cell destruction, and of spreading to the neighboring inguinal nodes, gives better protection than one which produces hardly any appreciable and purely localized tissue changes; (4) that cultures derived from cold-blooded animals and which grew only at room temperature, as used above, have brought about no appreciable degree of immunity. (5) The chemical changes produced in killing the bacilli by heat in the first experiment cannot wholly explain the lack of protective power of the vaccination with dead bacilli.

*American Medicine, September 30, 1905.*

**Large Desmoid Tumor of the Abdominal Wall.**—E. E Montgomery and P. B. Bland report this case, occurring in a woman 26 years of age, married at the age of 19, and the mother of two healthy children. The tumor first appeared seven years before operation, gradually increasing for the first six years, but during the last year it grew very rapidly. The tumor after removal measured 76 cm. in its greater circumference, and 66 cm. in its lesser circumference. It weighed 19 pounds. It had its origin in the sheath of the right rectus. It was of a pearlish pink color, of dense consistence. Microscopically it was found to be composed of young connective tissue cells. The blood vessels were numerous, and in many areas the vessel walls seemed to be composed of tumor elements.

**Surgery of the Stomach.**—Bevan deprecates unnecessary operations due to too great enthusiasm of qualified operators, and the undertaking of this class of work by men who are not fitted. He then discusses surgical treatment of gastric carcinoma, and of gastric ulcer, complications and

sequels. He urges for carcinoma radical removal or non-interference, and is not in favor of the palliative measure of gastroenterostomy. In technic, he prefers the suture to the use of either Murphy's button or the McGraw ligature. Ulcer is the province of the surgeon only after intelligent medical treatment fails. The complications and sequels of stomach ulcer which demand surgical treatment without question are perforation, obstruction of the pylorus, hour-glass contraction of the stomach, and such secondary conditions as perigastric adhesions and abscess, subphrenic abscess, etc. One of the sequels which must be considered is that of a carcinoma developing in the ulcer. There can be but little doubt but that this does occur very frequently. Pyloric obstruction and dilatation of the stomach furnish by all odds the most satisfactory groups, as far as the results from surgical treatment are concerned; these cases should practically all be submitted to surgical operation.

**The Vagovisceral Reflexes with Special Reference to the Vagostomach Reflex.**—Dr. Albert Abrams avails himself of the physiological fact for clinical purposes, that the vagus nerve may be subject to mechanical stimulation by directing the patient to draw the head slowly and forcibly backward. Hypertension of the cervical muscles thus elicited results in inhibiting cardiac action which proves of inestimable service in the differentiation of heart murmurs. The same maneuver enables one to recognize an asthmatic lung even in the interparoxysmal period. In the norm, when the head is thrown backward and maintained in this position, percussion over the manumbrium sterni yields a dull or flat sound, whereas in the asthmatic lung the percussion sound over the latter region remains unchanged. The latter sign the author refers to as the 'tracheal traction test." He finds that the lower stomach border by the identical maneuver may be accurately defined by the dullness supplanting tympanicity by percussion. This, taken in conjunction with his "stomach reflex," which causes a recession of the lower border of that organ, enables him to determine the motor power of the stomach as well as the actual lower border of that organ. In other words, after defining the lower border of the stomach by percussison during the time the head is extended, he directs the patient to relinquish extension of the head and proceeds to concuss the Traube area. The difference between the percussional areas obtained after both maneuvers is in direct ratio to the motor power of the organ, which varies in the norm from 2 to 4 cm. The accuracy of his results has been controlled by the *x*-rays, gastrodiaphrane and the conventional methods of determining the lower stomach border.

**Manifestations of Lithemia in the Spine and Lower Extremities, Simulating Orthopedic Conditions.**—Prescott Le Breton calls attention to a group of cases occasionally seen by the general practitioner, in which the chief complaint is pain and tenderness in the feet or back, simulating a flatfoot or spinal condition. On examination by the orthopedist the underlying cause is found to be lithemia, or that state of disordered nutrition in which there are gastrointestinal symptoms, cardiac irregularity, diminished or increased secretion of urea, with anemia and neurasthenia. In addition, tender points over the muscles and various peripheral nerves may be found. General treatment cures these patients, instead of flatfoot plates or jackets.

**Infection of Chinese with Asiatic Blood Fluke.**—H. G. Beyer says this case is interesting, as it represents the second of the kind recognized from China and, at the same time, establishes a new locality for the parasite to which its further spread and distribution may be traced. Its presence in the Philippines may now be discovered at any time. The report is accompanied by a complete clinical history furnished by Dr. O. T. Logan, of Changteh, China. The identity of the parasite discovered in the present case, with the one obtained by Catto from a Chinaman having come from the province of Fukien to Singapore, was easily established by a comparison with one of Catto's original preparations, fortunately in the possession of Dr. Stiles. Perhaps the chief distinguishing characteristics of the egg are its size and the absence of a spine. The average obtained from nine of the eggs is 72 microns in length and 48 in breadth.

*Journal of the American Medical Association, September 30, 1905.*

**Cancer of the Mouth.**—W. W. Grant criticises the usual operation for mouth cancer as disfiguring and only suited for small growths with large mouths. He makes, instead, two straight incisions, one on each side of the growth, connected by a straight transverse incision at the base, leaving a quadrangular space to be filled by flaps. These are formed by incisions downward and backward from each lower angle of the wound, and are separated from the inferior maxilla and united in the middle line. The angles of the mouth are incised and covered with underlying mucous membrane, no denuded surface is left, and no grafting is necessary. The chin tissues are left undisturbed unless diseased. The oblique lateral incisions permit the removal of the submaxillary glands (except the submental which may require a second incision), and the exploration of the anterior triangle can be made. He compares this method with others now employed, and points out the advantages claimed for it—the removal of the glands through the flap incisions, the absence of denuded surfaces left, the slight tension of the lip, the better cosmetic results, etc. Five cases are reported.

**Excision of the Cervical Portion of the Esophagus.**—W. I. Terry reports a case of extirpation at one operation of both submaxillary glands, the remnant of the epiglottis, the hyoid bone, the anterior three-fourths of the esophagus to below the thyroid and the thyroid gland itself in one block of tissue. The posterior one-fourth of the esophagus, being uninvolved in the malignant growth, was left to furnish a mucous covering to the cervical vertebræ, a result which was obtained. The patient had undergone four previous operations, including two laryngofissions and a laryngectomy. Convalescence was uninterrupted and the patient was up and about by the fourth day after the operation. At latest report, about three and a half months after the operation, the patient was able to do all sorts of farm work and had gained in weight, being only three pounds under his normal figure of 150 pounds. The trachea was kept open by a constantly worn silver tube. He masticates his food and swallows it through a funnel-shaped rubber tube suspended above to the opening of the pharynx, the narrowed portion below entering an inch or two into the esophagus.

**Cancer.**—W. L. Rodman considers the parasitic theory of cancer as far from being proved, and also thinks that there may be some overestimation of the increase of the disease in recent times. If parasites are present, it is probable that they play a secondary part and are not the primary cause of the disease. The transmission of a cancer from one individual to another, he believes, is simply a case of successful grafting, and the rare, if not unheard-of infection of operating surgeons is also against the parasitic theory. The old theory of continued irritation of epithelial structures is still largely valid, and the minimizing of heredity has, as with tuberculosis, been carried too far. Probably more than one cause is usually operative. Comparatively little of what is written or said in regard to precancerous conditions, Rodman thinks, is based on indisputable facts. Paget's disease of the nipple, for example, is generally believed to be precancerous, but he considers the association is infrequent, and when it does occur the areolar disease is apt to be secondary. He also questions any necessary connection between phimosis and cancer. That gastric ulcer is often followed by cancer is undeniable, and that cancer of the cecum frequently follows repeated appendiceal infection he has not the slightest doubt. In case of suspicious mammary tumors prompt operation is certainly desirable and exploration is easy, safe and quick. In any case, a thorough operation should be prepared for as the safest course. Three conditions of mammary cancer are too much overlooked, he thinks: 1. The pathologic character of the growth influences the prognosis, scirrhus and ancephaloid being less favorable than adenocarcinoma. 2. The age of the host; metastases being more rapid in the young. 3. The location of the growth, the inner hemisphere of the gland, on account of the danger of mediastinal infection, being most dangerous and requiring most prompt operation. Rodman emphasizes the importance of complete operation in cancer, and holds that the supraclavicular glands should be explored and removed if enlarged, in all cancers situated in the upper part of the mammary gland.

**Extremely Long Pregnancy.**—J. Arthur Lamb gives an account of a case of pregnancy which lasted, dating from the last menstruation, 339 days; and dating from the last coition 313 days. These data seem to be well fixed. The cause attributed by him was a cranial deformity of the fetus, interfering with prompt natural delivery, the exact nature of which is not stated, though it is said that the brain was exposed, giving the suggestion of a breech presentation. It would have been interesting, he remarks, to have known how long this case would have gone had not quinine been given to cause uterine contraction.

**The Musical Heart.**—J. M. Patton gives an account of the well-known musical heart case so familiar to medical clinics and mentioned in the lay press of late years. The special peculiarity was a distinct musical note occurring with the cardiac systole, and heard all over the precordial area with varying intensity, but plainest from the second rib to the fifth interspace along the left parasternal line. The diagnosis made when first seen was double aortic and double mitral lesions with the musical notes originating in the left ventricle and probably due to some abnormal condition of the chordæ tendineæ. The patient was observed by Patton at intervals for twelve years. The musical sound disappeared during the last few months of life. The autopsy

bore out the diagnosis and Patton considers it probable that the musical sound was attributable to the thickened chordæ tendineæ, which were found broken and floating loosely in the ventricular cavity. This, he thinks, will account for the sudden disappearance of the murmur during life. The greater tension on these during systole, which would be the result of their thickening, might easily produce in cords of such length the high-pitched and sustained musical note that was heard. If musical notes require, as here assumed, the rapid vibration of some organized structures of the heart, we must admit they have a different prognosis and a much more serious import than ordinary blowing murmurs. Patton has observed them several times before the fatal termination of severe endocarditis. He, therefore, thinks this case illustrates the fact that they indicate a more serious involvement of cardiac tissues than do the ordinary murmurs.

*The Lancet, September 23, 1905.*

**A Case of Blackwater Fever Treated Without Quinine.**—D. Donald reports the case, his patient being a young man who had returned from Africa, and who was, when first seen by the author, in a state of collapse. Treatment consisted of hot fomentations, champagne, and hot milk, to which phenacetin, caffeine, iron, and strychnine with beef essence were added p. v. iv. The patient responded well, was gradually placed on a more generous diet, and was able to be out of bed on the fourteenth day from the commencement of the attack. No quinine was used at any time, and there was no doubt as to the accuracy of the diagnosis.

**The Treatment of Strychnine Poisoning and of Tetanus by Spinal Anesthesia.**—From a general consideration of this subject, and from certain experimental work, A. E. Russell lays down the following propositions: (1) Strychnine convulsions occur only when the spinal cord receives afferent impressions. If these be cut off by section of the posterior roots the spasms do not appear. Spinal cocainization or eucainization causes a temporary physiological "section" of the posterior roots and experimentally in animals controls the strychnine convulsions. Its trial in cases of strychnine poisoning in man is therefore strongly indicated. (2) The spasms of tetanus are very similar to those produced by strychnine, and are also markedly increased by afferent impressions. One case of tetanus was successfully treated by the author in the way described, and he believes that the method is worthy of further trial. Eucain is preferred to cocain because the solution can be boiled, and the complete sterilization of any fluid injected into the spinal theca is most important.

**Forty Consecutive Cases of Fracture of the Patella, Treated by Wiring.**—This series of operations was seen by Mansell Moullin throughout a period of eleven years. At first he used the plan on only young adults, but more recently he has used the wiring plan in every case except one, that of a case of refracture in an enormously stout woman, in whom no operation of any kind was advisable. In the first twenty-eight cases various methods of wiring were tried and none found satisfactory, except that of Barker, which consists in passing a wire vertically around both fragments, through the ligamentum patellæ below and the tendon of the quadriceps above, and twisting the ends on the cutaneous surface. This plan appeared to give good bony union, but in the submission of the cases to the test of the x-ray when it was introduced to surgery, it was found that the apposition of the fragments was far from ideal, and in one or two instances the results were distinctly bad. In the last twelve cases the author has used the open method. Operation has been performed on the third or fourth day after the accident when the patient has become more or less reconciled to bed and the swelling of the joint has ceased to increase. A semicircular flap is raised from over the fragments, and all the blood clot is carefully turned out. Each fragment is drilled in such a way that the wire does not project through the cartilaginous surfaces. A single stout silver wire is passed through and the ends are twisted together until the fragments are in exact apposition, cut short, and buried. No antiseptic is allowed to touch the interior of the joint. There is no occasion to wash it out, as the blood, being all coagulated, can be removed with ease by means of a scoop and forceps. The torn fascia on the cutaneous surface of the patella is then united with catgut and one or two catgut sutures are used to join together the aponeurosis on either side if it has been extensively lacerated. No drain is inserted, but the angle of the cutaneous incision is left a little open in case there should be any oozing. No splint is used. Deep and superficial dressings are applied and the knee is firmly bandaged. On the third or fourth day the bandages and the superficial dressings are removed and are replaced by a lighter bandage, and the patient is encouraged to flex and to extend the limb more and more each day, until by the end of the fortnight it can be bent to a right angle. Massage is commenced early and the patient is up before the end of the third week. In none of the forty cases was there any post-operative rise of temperature.

**Paratyphoid Fever.**—The paper of F. P. Mackie consists of an elaborate report of one case and certain references to the literature of the subject. This patient was a young officer, aged 22 years, without any malarial history. He had never received anti-typhoid serum. The febrile period of the disease lasted over five weeks and presented somewhat atypical typhoid phenomena, while convalescence was tedious, as the patient was not able to travel until the end of the twelfth week. The author believes that the designation of "paratyphoid" is correct in this case, inasmuch as clinically the disease ran a course not unlike that of many cases of true enteric fever, and yet the serum failed to give the characteristic reaction with no less than three stains of the Eberth bacillus. Instead of the characteristic somnolence and apathy there was a hyperacidity, an almost morbid inquisitiveness, and an apprehensive watching of the most trivial details of nursing. Again the temperature curve was abnormal; the wide diurnal variation within a more or less limited range suggesting a septic rather than a typhoid process. This type is seen during the fourth week of an average typhoid case and corresponds to the time when the ulcers are bare and absorbing small quantities of septic material. In the case under consideration this septic type persisted from the beginning, and in the fourth week the high rises and sudden falls and the rigors and sweats suggested either malarial fever or pyemia. The former was disproved by blood examination, and there was no reason to suppose that true pyemia was ever present. The abdominal symptoms were less marked than usually occurs in a case of such severity. It is true gurgling in the right iliac fossa was marked from the first, but the abdomen was never more than slightly full, and the spleen was not enlarged at any time. The tongue never became dry and sordes never formed. The case was a sporadic one; there was no enteric fever at the place in which he had been located, and twenty-five days had elapsed since he left that station before the first symptom occurred.

*British Medical Journal, September 23, 1905.*

**The High Range of Normal Temperature and Pulse Throughout the Puerperium.**—E. Hastings Tweedy believes that there is no myth in the medical profession more common than the belief that puerperal sepsis has long since ceased to become a scourge. He says that it is not until we compare figures by the thousand that the superiority of the present day methods asserts itself. If judgment be not based on a death standard alone, this superiority is found to be overwhelming. The writer gives some very interesting figures, taken from the early history of Rotunda Hospital. It would seem from these ancient statistics that the majority of women will survive the processes of childbirth under the most disadvantageous circumstances. However, if the well recognized principles of asepsis are not followed out, a small minority only will pass through this ordeal unscathed. It is almost universally conceded that the processes of childbearing have none but the most transitory effects in elevating the temperature above that which is considered normal in health. It is a great mistake, however, to estimate morbidity by any arbitrary range of temperature when taken without consideration of the pulse. The writer urges that some common basis for determining morbidity other than that of the unsatisfactory temperature limit be decided upon. For in this way only can a clear insight be gained into the efficiency of modern methods. A septic condition will show itself by an acceleration of the pulse as well as by a rise of temperature. It is a most convenient plan in the arrangement of bed charts to make these two records apparent at a passing glance. This method is observed at the Rotunda Hospital. The high range of normal temperature is placed at 99 degrees F., and that of the pulse at 90 beats per minute. Even a mild condition of septic absorption will result in the overstepping of these limits, and thus attention is promptly called to any approach of danger. No case is entered on the morbid lists until the abnormal condition has made itself apparent for twenty-four hours. Neither are the irregularities of pulse or temperature which so often occur within twenty-four hours of the period following delivery, taken into account.

**Some Complications and Degenerations of Uterine Fibromyomata.**—S. J. M. Cameron calls attention to these various conditions, illustrating his article with cuts representing different tissues described. The first case mentioned is one of primary carcinoma of the tube attached to a uterus containing fibromyomata. The writer states that it may have been secondary to a hydrosalpinx, as many of the anatomical and pathological appearances present are found in that condition. The next compli-

cation discussed is the sarcomatous growth. Some authorities have denied the possibility of the occurrence of sarcomatous degeneration of fibroids. The report of various cases proves this view to be erroneous. These tumors growing in the uterine wall (muscular) may start in the areas affected by fibromyomata. They may be submucous, interstitial, or subperitoneal. When they result from the degeneration of a fibroid tumor they may involve it partly or totally. It might, owing to the vitality and extent of the growth, be a matter of great difficulty to state precisely in which of these areas the growth had arisen. Generally speaking, the sarcomatous area is softer than the fibromyoma in which it occurs. Sometimes these sarcomata can be shelled out exactly like a fibromyoma. A fair average of the association of adenocarcinoma of the uterine body with fibroids seems to be from two to three per cent. Carcinoma of the vaginal part of the cervix with uterine fibroids is far more uncommon. In a case described in this paper, pain was a very distressing symptom. In cases of fibromyomata, there is often marked increase in the size of the ovarian and uterine arteries. It has been noted that uterine fibroids are often accompanied by a blowing murmur, the seat of which has not been accurately described. Cystic degeneration occurs fairly often in fibroids. This change may be either diffuse or localized. As to thrombosis, in every case studied by the writer in which it appeared to occur, microscopical examination showed the clot to be of recent formation. The writer mentions the interesting fact that tumors undergoing cystic and myxomatous change give an impression of a bullock's heart shape to the examining hand on the abdominal wall. He gives a description of localized telangiectatic condition of a fibroid with tuberculous disease of the ovaries and tubes. Finally, adenomyomata of the uterus are discussed. These growths do not recur if removed, but such tumors have a decided tendency to become malignant.

*Berliner klinische Wochenschrift, September* 11, 1905.

**Direct Methods of Examining the Upper Air Passages.**—Meyer describes the instruments and the technique necessary in examining the larynx, trachea, and bronchi by means of autoscopy and bronchoscopy. The former is accomplished with special tongue depressors of various sorts, provided with means for electric illumination, while the apparatus for bronchoscopy is more elaborate and comprises a set of tubular specula of various diameters and lengths, intended to be pushed into position either through the larynx or through a tracheotomy wound. Meyer, who has performed over one hundred endolaryngeal operations on children by the direct method, believes that in most cases it will be found the preferable procedure in dealing with young patients, though at times he admits the laryngeal mirror will prove more useful. Trial must be made in each case in order to learn which plan is more suitable. He describes a number of cases in which bronchoscopy was successfully employed for diagnostic or operative purposes, particularly in cases of struma, in which the presence of intrathoracic growths was suspected and detected by this means. In one such case dyspnea due to pressure stenosis was greatly relieved by systematic dilation carried out by the introduction of a special instrument. Although not going so far as Killian who foresees tamponade of the lung as a treatment for hemoptysis, Meyer believes that great possibilities are open to the development of these methods, particularly as adjuvants to pulmonary surgery.

**The Protoactivity of the Blood.**—Schälpfer describes experiments made to determine the properties of the blood and hemoglobin in regard to sunlight. The blood of rabbits was collected in Petri dishes and then placed in a camera obscura in close proximity to photographic dry plates. The plates were covered with black paper in which a triangular opening had been cut on the sensitive side. On developing the plates after exposure of a number of hours the negatives gave evidence of some photodynamic property in the blood, so that the outline of the triangle could be perceived. The blood of albino rabbits gave clearer results than that of brown animals, a fact which the author explains by assuming that the pigmented skin of the latter offers a greater resistance to the passage of the sun's rays than that of the former. While admitting that the results of these experiments on rabbits' blood cannot be transferred without modification to human beings, the author considers that a most interesting field is opened up regarding the significance of the cutaneous pigment in different races, in certain affections, such as Addison's disease, etc., and he urges further study of this subject in order that definite principles may be formulated for the practice of phototherapy.

*Deutsche medizinische Wochenschrift, September* 14, 1905.

**Results of the Operative Treatment of Carcinoma.**—Dollinger summarizes the results obtained in the University Clinic of Budapest. The total number of cases operated for cancer during the four years from September 1, 1897 to September 1, 1901, was 226. Circular letters were sent to all of these patients and 175 replies were received. In making up his statistics Dollinger included those cases in which death occurred in conjunction with the operation through some complication such as sepsis, pneumonia, etc., and also those dying later on of some intercurrent disease, as although these groups are often omitted in such classifications, he does not believe that they should be excluded from the mortality lists of the disease. On the other hand, while it is likely that the proportion of those dying of carcinoma is greater among the patients from whom no replies are received than among those who respond to inquiries, there is nothing possible but to leave them out of the reckoning. Dollinger's results show freedom from recurrence during three years in 40 per cent. of 175 cases, and during five years in 41.25 per cent. of 80 cases. Since the Halstead-Kocher operation has been employed the percentage of cures in carcinoma of the breast has risen from 16 per cent. to 41.17 per cent. The statistics cover cases of all varieties of carcinoma except that of the pelvic organs, which comes in the domain of the gynecologist.

**Spirochætæ in Syphilis.**—Scholtz reports on fifty cases examined for the spirochæta pallida. Thirty-seven of the number were syphilitic, and among these the spirochæta pallida was found twenty times and the refringens five times. In thirteen control observations on non-syphilitic material of various sorts the spirochæta pallida was found once and the spirochæta refringens seven times. The author assumes a very conservative attitude in discussing the significance of the organism, and says that while its presence in syphilitic tissues is very striking and worthy of consideration, there is still much lacking to the proof of its etiological relation. The fact that the spirochæta pallida was found in large numbers in a case of pointed condylomata, and its infrequency in uninjured syphilitic papules at least indicates the necessity for caution in interpreting its position. Even if the spirochæta had no causative relationship with syphilis its frequent and almost exclusive appearance in this disease might be readily explained, since the tissue changes in syphilis are so specific that they might easily furnish an especially suitable habitat for the spirochæta pallida. Grouven and Fabry publish notes on twenty-one cases examined for the spirochæta. The organism was found in all but six cases, but it was somewhat doubtful whether all of these were really syphilitic. While certainty can follow only successful cultivation of the organism, the evidence so far seems greatly in favor of the etiological relationship of the spirochæta pallida to syphilis.

*French and Italian Journals.*

**Preservation of Living Fish.**—Buisson speaks of the difficulty, especially in summer, and in spite of the rapid methods of transportation, of obtaining, in towns far from the seashore, fish which are fresh enough for safe eating. Billard and Bruyant, naturalists, have some months ago, discovered that a certain green alga—microscopical—propagates itself very easily and rapidly in water where it is planted, and preserves it almost indefinitely in all its purity. It colors the water an intense green. These investigators have succeeded in keeping alive in a vessel of this water, for six weeks, the spawn of trout, which, as is well known, are extremely delicate and which are very greedy for running water. The young fish have been transported in this water on a journey of seven hours on the railroad, without the death of a single fish. Evidently this alga is of value through the function of its chlorophyle, decomposing carbonic acid produced by the bronchial respiration of the fish, and giving up to the water the necessary oxygen. Besides this, it acts like a yeast, decomposing the excrements or toxins elaborated by the fish and renews for them the conditions necessary for the functioning of their organisms. —*La Normandie Médicale*, August 15, 1905.

**Pulmonary Gangrene in an Infant Eighteen Months Old.**—Thirion observed this case. Pulmonary gangrene is rare in young children, especially in those under two years of age. The child whose case is here reported was brought to the hospital with grave pulmonary symptoms, and the diagnosis of tuberculous bronchopneumonia was made. A focus was noted at the right apex which was thought to be a cavity. The illness had followed an attack of measles six weeks before. Although the child was carefully treated at home, it gradually became worse, and was put into the hospital. On the day following its entrance, a fetid odor was noticed, but it was supposed to be due to the diarrhea from which the child suffered. Death occurred on the following night. Tuberculous bronchopneumonia was discovered at autopsy. The right apex was found to be gangrenous. The writer remarks that it seems remarkable that this gangrenous condition did not give any sign of its presence till the last hours of the child's life.—*La Presse Médicale*, September 9, 1905.

# Book Reviews.

The Principles and Practice of Medicine. Designed for the Use of Practitioners and Students of Medicine. By William Osler, M.D., Fellow of the Royal Society; Fellow of the Royal College of Physicians, London; Regius Professor of Medicine, Oxford University; Honorary Professor of Medicine, Johns Hopkins University, Baltimore; Formerly Professor of the Institutes of Medicine, McGill University, Montreal, and Professor of Clinical Medicine in the University of Pennsylvania, Philadelphia. Sixth Edition. New York and London: D. Appleton & Co., 1905.

It is hardly necessary or possible to review a book so well known as this, which is recognized as in many respects the best individual treatise on general medicine that we have in the language, ranking with Flint, and Watson, and Bristowe, and Niemeyer of the olden times. The author was always regarded as one of the best of diagnosticians, and so far as this depended upon knowledge rather than intuition he has done what he could to impart the secret of his success to his readers. In pathology also he is well versed, and the sections on pathology and morbid anatomy in the several chapters are unsurpassed in any other treatise of medicine.

The weakness of the work is due to Osler's black, hopeless, helpless therapeutic pessimism. Concerning the antitoxin treatment of diphtheria he does cautiously admit that "there are no reasonable grounds for skepticism on the part of intelligent practitioners"; he calls syphilis "one of the most amenable of all diseases to treatment"; he goes so far as to say, concerning the salicyl compounds in rheumatic fever: "There can be no question as to their efficacy in relieving the pain in the disease"; and he actually says boldly, as though without fear of contradiction, that "in quinine we possess a specific remedy against malarial infection." But we think we have included in this list all or nearly all his admissions of therapeutic faith; in most cases he either denies the efficacy of any treatment, especially drug treatment, or is carefully noncommittal. This is a great pity, for it renders the author an unsafe guide in the most important and practical part of medical science.

The several diseases are treated of under general sections, such as diseases due to animal parasites, specific infectious diseases, the intoxications and sunstroke, constitutional diseases, etc. There are, however, some apparent inconsistences, such as the separation of malaria from relapsing fever and from yellow fever. It is true the specific organism of the latter disease has not been positively discovered, but if there is any force in analogy one must believe that this organism is an animal; and the spirochæte of relapsing fever is surely a protozoan parasite. On page 6 is a curious slip implying that the ameba of dysentery is a bacterium.

There are but few illustrations, chiefly temperature charts and diagrams of the cerebral centers and motor and sensory paths in the cord. The print is clear and grateful to the eyes, and the binding is such as to allow the book to lie flat when opened at any page—front, back, or middle.

Treatise on Orthopedic Surgery. By Edward H. Bradford, M.D., Surgeon to the Boston Children's Hospital; Consulting Surgeon to the Boston City Hospital; Professor of Orthopedic Surgery, Harvard Medical School; and Robert W. Lovett, M.D., Surgeon to the Infant's Hospital and the Peabody Home for Crippled Children; Assistant Surgeon to the Boston Children's Hospital; Assistant in Orthopedic Surgery, Harvard Medical School. Third Edition. New York: William Wood & Co., 1905.

Since the appearance of the last edition of this work in 1899, considerable progress has been made in orthopedic surgery, which has necessitated extensive changes in the present, the third edition. This applies particularly to the chapters treating of congenital dislocation of the hip, of scoliosis, of traumatic and nontraumatic coxa vara, and of nontuberculous diseases of the joints, as it is in the study of these subjects that the greatest advances have been made. A new chapter is also added, giving the details of orthopedic apparatus, which will prove of signal value to the general practitioner in the treatment of these conditions. The liberality with which the book is illustrated is one of its valuable features, there being included in its pages 592 cuts, mostly photographic reproductions of a superior quality. Both authors have achieved distinction in their specialty, and the extensive clinical experience upon which much of their writing is based gives to the work the stamp of authority.

The Diagnosis of the Diseases of Women. A Treatise for Students and Practitioners. By Palmer Findley, B.S., M.D., Assistant Professor of Gynecology and Obstetrics in the Rush Medical College; Assistant Attending Gynecologist to the Presbyterian Hospital, Chicago. Second Edition, Revised and Enlarged. Philadelphia and New York: Lea Brothers & Co., 1905.

The necessity for a work of this nature, of which there are numerous examples in the other branches of medicine, must be apparent, and yet this is believed to be the first and only book of its kind in the English language. In the effort to supply this desideratum, the author states that he has aimed to satisfy the requirements of those who have felt the need of more comprehensive and practical information than can be given in the general text-books on gynecology. Dr. Findley bases his work on the assumption that a recognition of the pathology of the pelvic organs constitutes, in large measure, the diagnosis, and for this reason he has incorporated a thorough discussion of the morbid anatomy and its clinical indications. Microscopical diagnosis is also given an important place. The new edition has been brought up to date and contains additional text and illustrations dealing with the present aspects of such important subjects as cystic degeneration of the ovaries, chorioepithelioma malignum, and diseases of the ureters and kidneys. The new chapters deal with the examination of the blood and bacteriological examination. The book is well gotten up and contains a large number of selected illustrations.

Color-Vision and Color-Blindness. A Practical Manual for Railroad Surgeons. By J. Ellis Jennings, M.D. (University of Pennsylvania). Formerly Clinical Assistant Royal London Ophthalmic Hospital; Professor of Diseases of the Eye, Medical Department Barnes University, St. Louis; Ophthalmic Surgeon to the Centenary Hospital, Ophthalmic and Aural Surgeon to the St. Louis and San Francisco Railway System, etc., etc. Second Edition. Thoroughly Revised with Illustrations. Philadelphia: F. A. Davis Co., 1905.

This is a very practical monograph on color-blindness and the methods employed for its detection. It is written by one who has a most thorough knowledge of the subject and speaks as an authority. The methods of value in the examination of color-vision are described in detail, the description being supplemented with a number of good illustrations. This second edition contains additions describing the methods of testing the form and light sense, the rules for the examination of sight and hearing of railway employees adopted by the House of Delegates of the American Medical Association, and description of the test lanterns of Williams and Thomson, of the semaphore charts of Williams and Black, and of Abney's pellet test for central scotoma. Not only to railroad surgeons and others who have to examine large bodies of men, but to all interested in the subject and desirous of knowing the usual methods for detecting color-blindness, this little work will be most serviceable.

The Problem of Life. How to Prolong Life and Retain Mental and Other Faculties. By Benjamin F. Felch, M.D. Chicago, 1905.

There is much sound advice in this little book, but it is given in a very disjointed and jerky fashion, and not in a way to satisfy the scientific student. It is not intended, however, for the scientist, and the average layman to whom it is addressed might with profit take the author's injunctions to heart. He is rather extreme in his aversion to tobacco, tea, and coffee, each and every one of which he apparently regards as more injurious than alcohol, but then, a man is just as well off without tobacco or a woman without tea, as with it. The only harm is such rabid hatred of tobacco as the author exhibits is that it may repel his readers who know that, smoked in moderation, it seldom does harm, and who may think his advice in other matters is equally based on prejudice.

Hysteria and Neurasthenia. By J. Michell Clarke, M.A., M.D. (Cantab.), F.R.C.P.; Professor of Pathology, University College; Bristol Physician to the Bristol General Hospital. Practitioner's Handbooks. No II. Edited by Harry Roberts. London and New York: John Lane, the Bodley Head, 1905.

The author presents a very well ordered outline of the prominent clinical manifestations of Hysteria and Neurasthenia, exceptionally well arranged when we remember what a chaotic series of pictures these ill-understood functional diseases present. He appreciates the incompleteness of our knowledge from an etiological standpoint, but gives excellent hints regarding the diagnosis and treatment of these conditions. Besides the excellent press work we note nineteen illustrations, most of them full-paged photogravures. The author has considered those interesting cases, so important from a medicolegal standpoint, of Traumatic Hysteria and Neurasthenia in an entirely separate chapter. The various hypotheses which are considered as probable by different writers as appertaining to the causes of these diseases are carefully weighed and fully given, and, although not yet satisfactory, serve to stimulate further research.

# Society Reports.

## ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES.

*Fourteenth Annual Meeting, Held at Detroit, Michigan, September 26, 27, and 28, 1905.*

(Special Report to the MEDICAL RECORD.)

FIRST VICE-PRESIDENT, LIEUT.-COL. ALBERT H. BRIGGS, N. G. N. Y., OF BUFFALO, N. Y., IN THE CHAIR.

FIRST DAY—TUESDAY, SEPTEMBER 26.

**Reports by Officers and Committees.**—The morning's work was devoted to the reading of these reports. The Executive Council recommended the following:

*Resolved*, That the Association of Military Surgeons of the United States hereby expresses its entire approval of and earnestly desires the enactment of the bill to increase the efficiency of the medical department of the United States Army, which bill was submitted by the Secretary of War to Congress at its last session; and

*Resolved*, That a copy of these resolutions be furnished to the Military Commission of the House of Representatives and Senate and House of Representatives of the United States.

This resolution was duly seconded and unanimously carried.

Major C. H. TODD of Kentucky, president of the Association of Medical Officers of the Army and Navy of the Confederacy, who was elected a member of this Association this year, was introduced by the chairman. Major Todd appeared in the uniform of the Confederate Army, and was warmly received. He said that he was the youngest grandchild of Isaac Shelby, who, in 1792, was the first Governor of the State of Kentucky, and the son of Charles S. Todd, who served in the War of 1812.

**Report of the Seaman Prize Board of Award.**—In the competition for the prize of $500, offered by Major L. L. Seaman for 1905, the Board awarded the prize to Major Jefferson Randolph Kean.

**The Prevention of Disease in the Army, and the Best Method of Accomplishing That Result.**—Major JEFFERSON RANDOLPH KEAN, U. S. A., presented this, his prize essay, which was read in abstract form by Major Borden, Professor of Surgery, Army Medical School. The first step in the study of the prevention of disease in the army was to ascertain what diseases most seriously affect its efficiency or cause the chief loss to the effective force. He divided them into preventable and non-preventable. If the sanitary rules laid down in Circular 1, of the Surgeon-General's office, in 1898, had been carefully followed, he said the camps would have been health resorts and the country would have been saved the melancholy lesson of more than 20,000 cases of typhoid fever in the army of 1898, with more than 2,000 deaths. No method of prevention could be efficacious which did not embrace the necessary executive machinery to procure its practical working.

*Medical Statistics of Armies.*—One table was shown giving the constant non-effective rate per thousand for the eight most important classes of diseases in the armies of England, France, Germany, as compared with the United States; and its most striking feature was the predominance of venereal diseases in England and America, as compared with the Continental countries. Dysentery, malaria, and skin diseases were higher in the English and American armies because of the larger proportion of troops in the tropics. Typhoid fever occupied an obscure and humble position in the statistical tables of peace times, as compared with its predominating and sinister importance in war.

*Diseases of Armies in War.*—The medical statistics of the Russo-Japanese war we knew as yet but little about. In no recent war had military secrets been so carefully guarded as by the Japanese in this war, but enough had been learned greatly to stimulate curiosity, and to emphasize the importance to armies of careful preparation for war. The First Army (Kuroki's), with a mean strength of 57,000 to 60,000 men, and an unknown number along the line of communication, had in the four months between the battles of the Yalu and Liaoyan, 28,278 admissions from the fighting forces, and 34,934 from the lines of communication; of these, 861 were dysentery, 101 typhoid, and 4,069 kakke, or beriberi. The Second Army (Oku's) in the seven months had from the active army 24,642 admissions, of which 342 were dysentery, 193 typhoid, and 5,070 kakke; 5,609 cases were sent back to Japan, and 40 deaths were reported at the front. The remarkably small number of cases of both dysentery and typhoid, with the compensating prevalence of beriberi, were interesting. In the Spanish-American war of 1898 it might be said in general terms for the volunteer camps of the United States typhoid fever was the principal disease; for the Philippine Expedition, malaria and diarrhea; while malaria and yellow fever were the chief morbific factors which in six weeks reduced the army of Gen. Shafter to absolute impotence. In the Boer War, which lasted two years, out of a total force sent to South Africa of 448,000 men, 12,911 died of disease; of these 6,177 died of typhoid and 973 of dysentery. The prevalent causes of admissions were, in order of importance, typhoid, diarrheal diseases, rheumatism, chiefly muscular, and malaria. In the Franco-Prussian War the Germans lost in killed, 17,255, and from disease, 14,904, in the active army; the total admissions per thousand for the first twelve months was 589. Typhoid fever caused 60 per cent. and dysentery 16 per cent. of all deaths from disease. The Civil War seemed to mark the beginning of a new epoch in the morbidity of armies, because the two infectious diseases which had before that time been the most formidable agents of destruction to the armies of the world did not appear, typhus and cholera. The more common camp diseases of recent wars which affect the efficiency of armies are typhoid fever, the diarrheal group, including dysentery, malaria, the respiratory group, rheumatism, articular and muscular, and venereal diseases. Of these the first three and the last must be considered to be preventable. The trench latrine should be restricted to temporary camps and emergency use. If the command remained longer than two days in one camp, lumber should be obtained, and each sink progressively improved so as to comply with the following: 1. It should be covered with either a tent or other roof, to prevent its being filled with rain. 2. In order to exclude flies the trench should be boxed in and holes constructed with hinge covers, the hinges being of either leather or canvas. 3. A bar running along above the seat should prevent the covers being raised quite to a right angle, thus making them self-closing and preventing squatting on the seats. 4. A urinal should be provided at one end or outside, which should be either a tub or a tarred trough leading to a trench. 5. Behind the seats should be a sloping lid which could be raised to permit of the use of dry powdered earth or lime. The ideal method of disposing of all camp wastes would be by incineration. Cultures would be brought from the latrines, etc., on shoes, and distributed on tent floors. Clothing and blankets would soon acquire it from these sources. The bacillus might be passed on by books, playing cards, and other articles in common use. The necessity of guarding against typhoid infection in water, milk, and other articles of food should not be minimized. Fly infection should be guarded against. Proper sterilization of water was most difficult. With regard to the freedom from typhoid and dysentery in the Japanese Army in Manchuria, he believed it to be due to (1) a strict observance of the sanitary regulations prescribed by the medical staff; or (2) have the Japanese a constitutional and racial immunity to these diseases; or (3) does their simple and chiefly vegetable diet produce intestinal conditions unsuited for the development of the *B. typhosus* and *B. dysenteriæ*, or a bacterial flora with which these organisms cannot successfully compete? The Japanese soldier on the march was quite as regardless of camp police, or of safe-guarding his water supply, as was

the American volunteer. Offal was strewed about and sources of water supply were used for bathing in a way that would shock European ideas. On the other hand, in camp life careful attention was paid to police and the usual sanitary precautions were taken. Diarrhea and dysentery were considered along the same lines as was typhoid fever.

*Administrative Agencies.*—However excellent were the sanitary regulations, and however wisely adapted by experience to meet the special limitations and needs of military life, they would not make an army healthy unless there was a proper adjustment and cooperation among the different agencies involved in carrying them out. These were (1) the medical department, which was the originating guiding and informing agency, which had the duty of caring for the sick, and of preventing disease. (2) The line officers beginning with the commanding officer, who must order and enforce the execution of general hygienic measures, and the regimental and company officers, who must understandingly execute general measures, and in addition must educate their men in matters of personal hygiene. (3) The soldier, who must be taught the simple rules of personal hygiene and must put them into practice. (4) The staff department, which was charged with the duty of providing the sanitary apparatus and supplies and the trained personnel for running them.

*Conclusions.*—He said the tendency of modern civilization being to shield men from the infectious diseases in early life, they were now more susceptible to them than formerly, when collected into armies. The two infections most to be feared in our army in time of war were typhoid fever and bacillary dysentery. These always appeared but were not formidable to moving commands unless these occupied foul sites or drank infected water. In fixed camps they were always to be dreaded, and the following precautions must be taken: The water supply, if not above suspicion, must be sterilized. The excreta must be destroyed or sterilized at once by the use of the Reed trough and excavator, or some form of incineratory. Urine tubs must be placed in the company streets at nights, and fouling of the camp site by this excretion prevented. The pollution of the camp in other ways must be prevented. Tents must be moved every week. Kitchens should be on the opposite flank of the company from the sinks. No camp should be occupied more than a month if possible to move it. Voluntary troops when mustered in should be given a careful physical examination. In order to carry out sanitary rules for the prevention of disease in the Army we should have the following machinery: 1. An adequate and well-trained medical personnel. 2. A system of instruction in hygiene for line officers. 3. Instruction of enlisted men by their officers in the elements of personal hygiene. 4. The establishment in the Army of a service of camp sanitation to be administered, preferably by the Medical Department. A division sanitary inspector should be at the head of this service.

**A New Hypodermic Syringe.**—Lieut. William W. Reno, U. S. A., presented this. He said that every hypodermic syringe now upon the market except the one described was incomplete, as outside assistance was needed, in the shape of water, mixing chamber and means of sterilization of needle. The one he presented was complete in itself, as sterile water, a sterile mixing chamber, and sterile needles always ready accompanied the syringe in a case no larger than the old style. Several improvements had been made in the instrument itself. The army had ordered several, and he said he would not be surprised if the army adopted it

**Routine Instruction in the Hospital Corps of the National Guard.**—Major William G. Bissell, Surgeon N. G. N. Y., presented this paper, which was read by title.

**The Efficiency of the Enlisted Man of the Hospital Corps, with Especial Reference to the National Guard.**—Major George M. Coates, N. G. Pa., said that the enlisted man of the Hospital Corps had, in times past, not been of the same quality, considering the work that he was called upon to perform, as the enlisted man of the line. The enlisted man of the Hospital Corps of the present day even, especially in the National Guard, was often found to be lacking in those qualities and attainments, instruction and training to properly fit him for his calling. Much might be done in the way of instruction of these men but, in the National Guard, there was a special field for selection especially in the cities, in the presence of medical students and internes who made most valuable men for military purposes. The special training they were receiving or had received should be supplemented by instruction in military hygiene, military surgery and First Aid and by drill. A corps composed of men of this character might be made still more effective and efficient by proper organization and by their being tested and worked together.

Capt. Myles Standish, N. G. Mass., Major E. F. Sommers, N G. Ind., Major A. R. Jerritt, N. G. N. Y., Lieut.-Col. Nathan S. Jarvis, N. G. N. Y., Lieut.-Col. L. B. Almy, N. G. C., Major B. H. Rogers, N. G. Ill., and Surgeon C. F. Stokes, U. S. N., discussed this paper.

**A Plea for the Unification of the Duties of Medical Officers of the Army and Navy.**—Surgeon Charles F. Stokes, U. S. N., entered this plea, which included medical officers of the naval militia and national guard, claiming that the basis of existence was the same, the preliminary requirements were alike, the service conditions somewhat alike, the service school instruction was along the same lines with modifications to meet the peculiarities of service afloat and service ashore. The aims, personnel and material should be as far as possible the same. *Esprit de corps* in and healthy rivalry between the various branches of the medical service should be encouraged. The Association of Military Surgeons was of peculiar value in that it brought together military surgeons for the purpose of discussing various matters of interest to them in which discussions were all on the same equal footing. The most important problem to be solved by military surgeons was the training and drilling of enlisted men in the working details of military hygiene and First Aid methods. The early education of the line officers in these matters was absolutely necessary. There should be one method and one routine, and he believed it a good and wise plan to establish a joint board, composed of experienced, liberal, and intelligent medical officers of the Army and Navy, Militia, National Guards, etc., who should teach what was necessary regarding hygiene, First Aid methods, etc. This should occupy at least fifteen minutes of every day and taken up as a routine matter, the same as drilling with arms. This drilling was clearly the work of the line officers. In summing up his paper, Dr. Stokes attacked Dr. Seaman very severely for many of the statements contained in papers read at the previous meeting of the Association and since. He called in question the accuracy of some of Dr. Seaman's statements and bluntly denied others. He believed that Dr. Seaman could do the cause of military surgery and military sanitation in this country no greater service than that of revising his statistics and correcting statements made by him which had misled the laity generally, and he would be most happy to render him any assistance he could.

**Dangers in Typhoidal Urine in Military Camps.**—Captain Charles S. Butler, M.V.M., read this paper, and said that in numbers of examinations made of urine in cases of typhoid fever in about 21 per cent. of them were the bacilli found in enormous numbers and in pure culture, and this showed the need of adopting some effective method by which all cases of typhoid should be treated. Among the methods advocated were (1) after the urine had been passed to treat it with carbolic acid, or other disinfecting chemical; (2) washing out the bladder with some antiseptic; (3) the administration by the mouth of some urinary antiseptic, such as salol, urotropin, etc., or some formaldehyde derivative. The first and second of these methods were impracticable on the field and at base hospitals. The third method was practical, easy, and most effective, preference being given to the formaldehyde derivatives.

**An Emergency Case for Field Work.**—Lieut.-Col. Leon-

ard B. Almy, C. N. G., showed the advantages of having a case for hypodermic medication on the medical officer's person, and he gave a description of his pistol cartridge-box case which was always on the belt.

**Mexican Transport Model for Carrying Wounded in Mountainous Countries.**—Lieut.-Col. Alejandro Ross, Mexican Army, gave a description with model of an appliance of particular service in the irregular terrain of Mexico which was submitted by the Professor of the Department of Transportation of the Injured at the Medico-Military School of Application of that country in which there were great variations in landscape.

Following a general reception at the Hotel Cadillac, there was a public meeting. Congressman Edwin Denby spoke for the State of Michigan, Hon. George P. Codd, Mayor of Detroit, spoke for the City of the Straits, and Major F. E. Jacklin, the only survivor of the 16th Michigan Infantry, spoke for Michigan in War. Dr. H. Mareshal, colonel in the French service and official representative of that government, spoke in French. This was followed by an address by the Dean of the Foreign Delegates, Surgeon -General S. Suzuki, of the Imperial Japanese Navy. After thanking them in behalf of the foreign delegates for the honor they had conferred upon them by inviting them to the meeting, he said that the United States was comparatively a young country, and yet he noted that for fourteen years the Army and Navy surgeons had been meeting yearly. No doubt they did this in other countries, but nowhere in the world outside of this country did the surgeons invite foreign delegates to sit with them. He hoped for the formation of an international association which would draw all of them nearer together. He followed his remarks with stereopticon pictures illustrating the Japanese surgical work.

SECOND DAY—WEDNESDAY, SEPTEMBER 27.

**A New Type of First Aid Dressing.**—Surgeon Charles F. Stokes, U. S. N., gave a description of a dressing, method of applying it, and spoke of the peculiar features which seemed to him desirable in first aid dressings. It was made along the line of simplicity and ease of application. It consisted of gauze, one yard long and three inches wide, in four layers; at each end was a pad or compress, wire bound, inside of which were two layers of bibulous paper. This somewhat rigid frame made its application easy. His real aim was to have a dressing that could be applied satisfactorily by the least intelligent man in the service. The whole dressing was a single piece secured without pins, and could be used when there were two wounds at different levels.

**A Series of First Aid Packets.**—Major George H. Halberstadt, Brigade Surgeon, N. G. Pa., gave a description of first aid packets especially devised for use in the Pennsylvania coal regions.

**Improvements in Splint Stretchers.**—Surgeon Charles F. Stokes, U. S. N., showed improvements that he had made. The stretcher consisted of a boat-shaped piece of iron mesh with two fracture boxes. In each gutter there were adjustable foot pieces which hooked on. Chains were placed on the sides, to which the bandages were fastened. The man could be splinted from head to foot, and therefore one in transferring the patient handled the frame, and not the man at all.

**New Suture Material.**—Colonel N. Senn, U. S. V., presented some absorbable animal material which was of interest. He called especial attention to iodized catgut, which he had used for two or three years exclusively, the ligature being as strong as silk. It would not be absorbed before twenty-one days. He had entirely abolished the use of silk ligatures, and had substituted linen. When silk was sterilized by boiling its strength was lessened, but the linen ligature could be boiled and reboiled without loss of its tensile strength. Whale, walrus, and other animal ligatures he was experimenting with, the fibrous condition found in these sea animals being adapted to use as ligature and suture material. Dr. Senn showed other material which was used by the Eskimo women in making clothes and mending boots; the delicate but strong fibrils could be teased out. It was very strong, and could be readily rendered aseptic. He also showed a vegetable fiber that he had found in New Zealand, which he believed would prove an excellent substitute for horse hair for superficial sutures, but not for deep suturing.

**A Proposed Regimental Medical Supply Table for the National Guard.**—Captain Samuel Cecil Stanton, N. G. Ills., considered the needs of the National Guard and the regulars, suggesting the best means of meeting the requirements of the former. What he presentd had been accepted by the Illinois State Guards and Reserves, and he hoped that the National Guards would accept it.

**Notes on Experiences During the Russo-Japanese Naval War.**—Surgeon-General S. Suzuki, of the Imperial Japanese Navy, read this paper. As surgeon-in-chief of the combined fleets serving on board the flagship *Mikasa* under Admiral Togo, he divided his experiences into two parts—the treatment and management ot the wounded, and the sanitary arrangements of the combined fleets.

*Treatment and Management of the Wounded.*—In February, 1904, before the fleets left Sasebo, he issued orders to the surgeons of all the fleets that aseptic treatment should be adopted in the treatment of the wounded in all the battles of the war then imminent, and also ordered the observance of conservative methods of surgery; amputations, etc., on board the warships were to be avoided as far as possible, and every preparation made for transferring the wounded to the hospital ships, for conveyance to the home hospitals, where complete asepsis could be enforced. The total number of casualties from February, 1904, to August, 1905, was 3,682; of these 1,891 were killed and 1,791 wounded, of which 117 died afterward. Of the 1,891 deaths, 1,445 were due to shipwrecks caused by submarine mines, and only 563 to wounds received in actual fighting. Of the 1,791 wounded, 647 received wounds requiring hospital treatment, and of these only 32 died. The rest were partly light cases, and partly cases requiring greater care. Their aseptic methods had been the same as those in general use. All dressing materials were sterilized by steam, and kept in closed tin cases; surgical instruments were boiled in soda solution; hands were washed in sterilized water, with soap applied by a brush. A solution of sublimate was next used, which was followed by another washing in sterilized water. While the action was going on nothing could be accomplished except the most urgent aid. When the action was over and firing ceased, the healing art could be applied. The severer cases were first taken, fragments of shell or pieces of cloth extracted, and, when possible, the skin sutured. Their experience showed that to cover a wounded surface with skin was a great protection to it. He believed that it was better to give temporary relief to the wounded than to meddle with complicated operations, and to transfer the patients as soon as possible to the hospital ships.

*The Location of the Temporary Surgery.*—His experience taught him that, in spite of certain drawbacks, the proper place for the surgery was below the water line. Care should be taken to provide good light, proper ventilation, and an elevator. A location for a surgery during the time of action in battleships and armored cruisers might be found on the lower deck, but this was still above the water line; lower down in the ship the difficulty was not so much to find a place as to provide proper ventilation and good light, and convenient means for carrying the wounded down. During the war their surgeries had, as a rule, been placed on the lower deck in battleships and armored cruisers, while in the smaller cruisers either the wardroom, the cockpit, or one of the large cabins had been used. In unprotected cruisers the sides of the surgery should be protected with canvas screens or mantlets. While the gunboat *Chokai* was engaged in assisting the land operations to the west of Port Arthur a shell burst quite near the cabin which was being used as a surgery, but the

canvas screens prevented the entrance of the shell fragments into the surgery itself.

*Receiving Place for the Wounded after First Aid.*—On battleships and armored cruisers the passages on either side of the lower deck were used and no provision was made for from sixty to seventy men. If more space was needed the only places suitable were far down below the water line, accessible only by steep and narrow ladders. In unprotected cruisers every part of the ship was exposed; as a rule, the wounded were placed on the lower deck. During an action every hatch was closed, causing much distress among the wounded. In such cases electric fans should be provided, and refrigerating machines should be carried.

*Carrying the Wounded.*—During the bustle and excitement of an action it was found to be impossible to put into practice all the men had learned. In about one-third of the cases first-aid dressings were applied to the wounds, and the men carried down on stretchers to the surgery; in the remaining cases the men were just picked up as they fell and carried straight to the surgery in the arms of their comrades. After an experience on the flagship *Mikasa* it was considered unwise to risk any long exposure on the upper deck, and from that time the wounded were carried to the surgery at once, without waiting to have their wounds dressed on the spot. Their experience was that no one kind of stretcher was adapted for all the requirements of naval service. Carriage by hand was frequently resorted to.

*Dressing Materials and Instruments.*—A large consumption of dressing material was unavoidable during action; they foresaw this and provided each ship with an abundance. None of the ships suffered from any such lack even after the battle of the Japan Sea, when they had to treat many Russians in addition to their own men. For instance, 220 Russian prisoners were treated on board the *Kasuga* after the battle with no shortage of supply. The new First Aid Package contained four pieces of sublimate gauze, twenty-four inches long, and folded in a package four inches square. The package was wrapped in Japanese paper and then placed in a loose bag of "shibukami," a stout Japanese paper fabric steeped in the juice of the bitter persimmon. This package was easy to open, and the large size of the gauze facilitated application.

*Protection of Persons.*—Hammocks were very useful for protective purposes, and they had many illustrations of the value of hammock screens, frequently finding imbedded in them fragments of shells and splinters which would have wrought much havoc. They were not easily set on fire. They could be used as life preservers as well, lives of many of their men having been saved by clinging to them. In order to prevent scalds and burns from exploding powder and steam, all parts of the body should be kept covered. Prior to an engagement the sailors were ordered to bathe and put on clean underclothing, as a means of protection against infection of any wounds that might be received. He attributed the rapid recovery from wounds to this precaution alone. The conning tower of a ship was not the safest place to be. Admiral Togo constantly used the compass bridge during action, both for observation and for directing operations, and did not receive even the slightest wound. The ears of the men were plugged with sterilized cotton, and the eyesight of gunners was always examined prior to an engagement. The firing of big guns irritated the eyes and impaired vision; every battery was furnished with a 1 per cent. solution of boric acid for the use of these men, who bathed their eyes with the solution whenever they became irritated by the smoke and gases

*Character of the Gunshot Wounds.*—The speaker said they had no definite classification of gunshot wounds, but the following list showed the character of the wounds fairly well Taking the table of wounds from the beginning of the war to the battle of the Japan Sea—there were. Contusions, 480; abrasions, 212; incised and punctured, 26; wounds with loss of soft tissue, 53; lacerated, 691; blind, 224; perforated, 113; pulverized, 43; mutilated, 129; burns and scalds, 129; contusion of labyrinth, rupture of tympanic membranes, 116; compound fractures, simple fractures and dislocations, 237; explosive, 570; asphyxia, 25; drowned, 716; total, 3,764. Wounds of the head, face and neck, 808; of the chest, 157; of the abdomen, 58; of the upper limbs, 625; of the lower limbs, 728; of the back, loin and buttock, 189; pulverization of whole body, burns and scalds of whole body, 527; asphyxia, 25; drowned, 716; total, 3,833. The great number of explosive wounds were inflicted at the time of the sinking of the *Hatsuse* and the *Takasago*.

*Health Averages.*—Health averages for the last three years in ships of the standing and other squadrons:

| | |
|---|---|
| Total percentage of sick | 3.87 |
| Total percentage of men in bed | 1.19 |
| Total percentage admitted into hospital | 0.66 |

Health average for 1904 in the combined fleets:

| | |
|---|---|
| Total percentage of sick | 3.32 |
| Total percentage of men in bed | 0.72 |
| Total percentage admitted into hospital | 0.26 |

Health average for January to June, 1905, in the combined fleets:

| | |
|---|---|
| Total percentage of sick | 3.01 |
| Total percentage in bed | 0.65 |

During war times there were more casualties, but less venereal disease. After referring to the scale of diet for the crew and the supply of provisions, he considered the

*Water Supply.*—He said that ships which possessed evaporators used distilled water for all purposes, and the supply had been in all cases sufficient. Destroyers, torpedo boats, and special service vessels were, as a rule, supplied from water-supply ships. There were two of these which could distill about 300 tons of water each per diem, and two water transports of 5,000 tons together, besides coalers and transports which served as auxiliary water carriers.

*Hospital Ships.*—They had two specially fitted hospital ships, each of about 3,000 tons, each containing 186 beds, of which 18 were for infectious cases and 12 for the officers. Patients were transferred by steam launches or boats and sick-men's hammocks were the most convenient vehicles for this purpose. The total amount of dysentery in the whole fleet amounted to 151 during the period ending June, 1905. Appended to the paper was a statistical table. (See page ? .)

Major THOMAS C. CLARK, N. G., Minn., offered a resolution that the thanks be tendered the Japanese Government for sending such distinguished surgeons of the army and navy to participate in the proceedings of the Association. This was unanimously carried.

Surgeon CHARLES F. STOKES, U. S. N., said that during the war with Spain he was on board the *Solace*. The plan of treatment advocated there was conservative and he condemned operating upon ships until after action, because of the pandemonium which existed, making aseptic technique impossible. A scheme of transferring sailors from battle to hospital ships was presented by diagram.

Medical Director JOHN C. WISE, U. S. N., and Fleet Surgeon T. LLOYD, R. N., also took part in the discussion.

**Military Headgear in Its Relation to the Health of the Soldier.**—Contract Surgeon HAROLD D. CORBUSIER, U. S. A., read this paper.

**Presentation of Insignia to Foreign Delegates.**—Presentations were made to Lieutenant-Colonel Alejandro Ross, Mexican Army; to Surgeon-General S. Suzuki, of the Imperial Japanese Navy; to Colonel W. J. R. Rainsford, R.A.M.C.; to Fleet Surgeon T. Lloyd Thomas, R.N.; to Lieutenant-Colonel J. F. Fotheringham, A.M.S., P.M.O., M.D; to Dr. W. P. Chung, Dr. Ho Kan Yuen and Dr. Tsui Ying Young, Chinese surgeons; to Lieutenant-Colonel Brown, I.M.S., and others.

**A Brief Sketch of the Evolution of the Medical Service of the British Army.**—Colonel W. J. R. RAINSFORD, R.A.M.C., read this paper, being a description of the changing

conditions which had appeared in the British Army Medical Service since the writer joined it in 1876.

**Experiences With the Russian Army in Manchuria.**—Colonel Valery Havard, Surgeon-General, U. S. A., Medical Military Attaché with the Russian Army in Manchuria, read this paper. From all his sources of information he had computed that the percentage of casualties (killed and wounded) at the four most important battles of the war (exclusive of Port Arthur) was as follows: Liaoyang (August 28 to September 5), Japanese 9 and Russian 9.47; Sha-Ho (October 9 to 20), Japanese 8 and Russian 24.33; Sandepu (January 20 to 30), Japanese 18 and Russian 16; Mukden (February 20 to March 16), Japanese 13.41 and Russian 32.89. The mean percentage for the Russians in the four battles was 24.21, for the Japanese 12.27, and for both sides together 17.5. The ratio of killed to wounded in the Japanese Army was 1 to 4.5, in the Russian 1 to 3.96, in both armies together 1 to 4.22. The estimation of Japanese casualties at Port Arthur (from Japanese sources) was given as 10,000 killed and 36,000 wounded, or 1 to 3.6.

*Artillery Fire.*—At Liaoyang, in certain exposed trenches, 75 per cent. of the wounds were by shrapnel shells. At the fights at Cape Mountain, Fenghwangsham and Antszshan Fort a Japanese surgeon ascertained that, on the Japanese side, 1,101 men were wounded by artillery and 3,025 by rifle, a proportion of 1 to 2.75, or 27 per cent. At the four engagements near Mukden he ascertained that 725 men were wound d by artillery and 2,158 by rifle, a ratio of 1 to 2.97, or 25 per cent. These numbers referred to the wounded only and not to the dead. Those hit by shrapnels caused a greater number of deaths than of those hit by bullets; therefore, the percentage by artillery fire would be found decidedly greater than as given. It was roughly estimated that at Liaoyang 50 per cent. of the Russian casualties were caused by artillery fire; at the Sha-Ho, 33 per cent.; at Sandepu, 12 per cent.

*Bayonet and Sword Wounds.*—The bayonet was by no means an obsolete weapon and must still be reckoned with. Before the battle of Mukden it was roughly estimated that 500 Russians had been killed and wounded by the bayonet, a ratio of less than 0.3 per cent. of total casualties. Among the Japanese the ratio was higher. According to a statement attributed to General Oku, of the Japanese wounded up to November 17, 1904, 85 per cent. were hit by bullets, 8 per cent. by artillery projectiles, and 7 per cent. by side arms. This ratio he considered to be erroneous and untrustworthy. At the battle of Yalu, out of 1,170 wounded, only 0.5 per cent. were put *hors de combat* by side arms.

*Disease and Hygiene.*—According to statistics that were official in the report of July 28, 1904, the ratio of sick, before the rainy season, up to June 13, was 32.82 per 1,000 of strength. On July 26, after the rainy season had set in, the ratio had increased to 37.42. On that date the number sick with contagious diseases was 1,117, including all cases of dysentery and diarrhea. There were only 34 cases of typhoid, 15 of typhus, and 9 of recurrent fever. The number of typhoid cases, however, rapidly increased up to 951 on August 26. On December 8, 1904, there remained in all hospitals and other sanitary establishments, 819 sick officers and 17,384 sick soldiers; on this date the capacity of all available hospitals in Manchuria and adjoining zones was at least 30,000 beds. On February 8, 1905, there remained in hospitals 873 officers and 17,892 soldiers. In the official report of General Trepoff for the period of the beginning of the war to the end of the year 1904 the total number of sick and wounded evacuated to Harbin and places east and west of it, was 130,439 officers and men. He said that during the year 1904 the total number of Russians killed in action or who died from their wounds could not have been less than 20,000 (exclusive of Port Arthur); during the same period the number of deaths from disease was only 2,730, a ratio of 7 to 1. During the year 1905 up to the close of hostilities, about May 1, two important battles took place with a resulting total of wounded that probably was more than 100,000. As to the comparative number of deaths from diseases and wounds it was approximately 6,000 and 47,000 respectively, or in the proportion of about 1 to 8, a result far transcending the most sanguine expectations of military hygienists. In Manchuria, among the Russian troops, he said that one might fairly have expected certain diseases to break out in epidemic form, such as typhoid, typhus, dysentery, cholera, smallpox, scurvy, etc. But not only were such epidemics absent but the usual camp diseases had not been prevalent; so that the health of the Russian army in the field during certain months was better than when at home in peace. Nearly all the drinking water was obtained from wells 20 to 40 feet deep. Most of the food and drink of the Russians was so prepared that infectious germs could not be transmitted. Both Japanese and Russians, although fed upon rations which American and English soldiers would reject with scorn, were men of vigorous constitutions. The Japanese attributed their physical and mental strength to their plain, frugal food, the free use of water, gymnastics, and temperate habits. The national alcoholic beverage, saké, was hardly stronger than beer.

*Projectile and Gunshot Wounds.*—The shells of the Japanese field artillery were of two kinds, the ordinary shrapnel shell, with range of 3,000 to 3,500 meters, and the shimose shell with range of 5,000 meters; the former were more numerous and did more damage. The Russian cartridge weighed 24 grams and its bullet was 7.60 mm. in diameter; it had an initial velocity of 2,000. The Japanese cartridge weighed 22 grams and its bullet was 6.50 mm. in diameter and had an initial velocity of 725. The following interesting statistics of work done at the battle of Turenchen (May 1, 1904) gave an idea of the relative proportion in which the parts of the body were hit: Out of 1,129 wounded, the lower extremities were struck in 416 (37 per cent.), the upper extremities 309 (27 per cent.), the chest 221 (19 per cent.), the abdomen 107 (9 per cent.), the head and neck 76 (6 per cent.). In perforating wounds of the chest (37) hemoptysis was always noticed, but subcutaneous emphysema was quite rare. Of perforating wounds of the abdomen, 25 cases came under treatment and no operation was possible or attempted. Within 12 days, 7 died, a mortality of 28 per cent. Some of these men had been carried 40 miles in rough carts; only a few were brought in on stretchers, and 8 arrived with peritonitis. That only 7 died was remarkable. The innocuousness of the Japanese bullet in abdominal wounds was wonderful.

*Wound Infection.*—That the infection of wounds depended upon the skin and clothing of the soldier chiefly was well shown by the striking difference in the proportion of infected cases between summer and winter. Thus, in the Mukden hospitals, hardly 10 per cent. of the wounds were infected in summer; while, in winter, hardly 10 per cent. escaped infection, despite the primary dressings applied to them in most cases. Of the two causes of infection, dirt and particles of clothing, he said it was quite probable that the first was much more common. He concluded that if the soldier was able to carry out all the prophylactic measures which military hygienists suggested, he should on the eve of battle take a warm bath with brush and soap, put on fresh, clean linen and don his cleanest and lightest uniform. The soldier should be well fed, but on the day of battle his intestines should be empty.

---

**Value of the Crochet Needle in the Treatment of Sinuses Due to Infected Ligatures.**—C. Jeff Miller advises the use of an ordinary crochet needle in removing silk ligatures that have been left in the abdomen after major operations, and have produced deep sinuses. It may also be useful for removing foreign bodies. The author has saved patients from the necessity of a second serious operation, when a sinus has been left over the seat of a ligature used in tying the ovarian pedicle. These ligatures are of silk, and are picked up by dragging the crochet needle gently along the walls of the sinus.—*The Medical Recorder.*

## MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

*Fifty-fifth Annual Meeting, Held at Scranton, September 26, 27, and 28, 1905.*

(Special Report to the MEDICAL RECORD.)

FIRST DAY—TUESDAY, SEPTEMBER 26.

THE Society was called to order at 9:30 by the president, Dr. ADOLPH KOENIG of Pittsburg. Prayer was offered by the Rev. Dr. James McLeod of Scranton. Mayor A. T. Connell welcomed the Society on behalf of the city. The address of welcome was given by Dr. Daniel A. Capwell, president of the Lackawanna County Medical Society. He mentioned as a prominent achievement of the medical profession the lengthening of the average life of every man, woman and child ten years. The presentation of the program was made by Dr. Gilbert D. Murray, chairman Committee on Arrangements. Visiting delegates were introduced from the medical societies of the States of New York, New Jersey, and Connecticut.

A meeting of the Executive Council was held immediately following the general session. The president appointed a business committee, and they at once assumed the duties assigned to them. The secretary's report showed the addition of two new county societies, and a net gain of 266 members during the year. The chairman of the Committee on Scientific Business reported a list of six formal addresses and seventy-one papers upon the program. The registration numbered 504.

The report of the Publication Committee showed the necessity for an increased number of copies of the *Pennsylvania Medical Journal* over the original number contracted for. Upon motion of Dr. Edward B. Heckel of Pittsburg the report was received and a vote of thanks was extended to Dr. C. L. Stevens, editor, for his untiring efforts in behalf of the best interests of the *Journal* and the Society.

Dr. HENRY BEATES, chairman of the Committee on Legal Matters, reported that the committee had been instrumental in amending the original act of assembly in such a manner as to place Pennsylvania second to no State in the standard of preliminary education of the medical student. To the penalty of fine, imprisonment had been added for those practising without license; also provision had been made for the revocation of license of those engaged in immoral practices. Through the efforts of the committee the Osteopathic Bill had been so amended that there were required the same qualifications for the proposed licentiates in osteopathy as in medicine, with the exception of major surgery. The committee had discovered that the Osteopathic Bill, while having incorporated these desirable features, contained a provision which placed in the hands of a majority of their proposed Board of Examiners the right to recognize the diplomas of any osteopathic college, and license such applicant without examination—a measure which manifestly would rob the apparently high standard examination of all value and establish an open door for any alleged osteopath to engage in practice without hindrance.

Dr. JOHN B. ROBERTS, chairman of the Committee on Revision of By-Laws, made the report of this committee. The revision consisted mainly in the adoption of the Model Constitution and By-Laws of the American Medical Association. The Executive Council was changed to the House of Delegates, whose function was practically the same. A provision was made in the By-Laws to establish medical defense against suits for alleged malpractice and for the institution of a charity fund to aid sick and disabled physicians, and the widows and the children of deceased physicians. A committee was appointed to consider the subject of the prosecution of physicians practising criminal abortion.

SECTION "A."

FIRST DAY—TUESDAY, SEPTEMBER 26.

**Address in Medicine.**—Dr. S. SOLIS-COHEN of Philadelphia delivered the Address in Medicine. The speaker said that, of course, therapeutics must depend upon diagnosis and diagnosis upon pathology, and that the physician must be thoroughly grounded in the fundamental branches back of pathology, but that it was, after all, the question of treatment which occupied the physician chiefly in his relations with his patients. He deplored the position of the profession toward therapeutics which permitted the growth of the nostrum evil, and thought this credulity was based upon faults in the medical college and in the preliminary education of the medical student. He called attention to the work done by the Committee on Pharmacy of the American Medical Association in analyzing a number of preparations offered to physicians, and employed by them. To begin at the bedside the study of a derangement of the complex organism called man the speaker thought quite as ridiculous as the attempt of an astronomer to study an eclipse of the sun without the basic principles of arithmetic. To understand the complex organism of man there must be an understanding of the elements making up the whole and their influences upon each other. Before this was attained there must be the thorough laboratory training in biology, in physics, and in chemistry.

**Present and Former Methods of Treating Children.**—Dr. L. EMMET HOLT of New York City in this paper said that the treatment of sick children exhibited two subjects of importance—dietetics and general hygiene—and that the nutrition of the child should be the first step in treatment. In the treatment of intestinal disorders he regarded as essential factors evacuation, diet, and rest. In the chronic disturbances in children beyond infancy a careful dietary, in his opinion, was the only treatment giving permanent results. Unless severe lesions were present, the majority of the other measures were useless. The neuroses he believed to have their origin in impaired nutrition. In pneumonia the greatest effort should be made to put the body into a condition of resistance. The question of fresh air he believed was too much ignored. In bronchopneumonia fresh air that was not cold should be abundantly provided. The use of two rooms alternately with the air first warmed he suggests as valuable in treatment. The thought which he emphasized was that a better understanding of disease and a broader knowledge of children showed that the greatest need was a more scientific and intelligent knowledge of practical dietetics and a better understanding of the condition of health and growth. Of greatest importance in acute and chronic disease, he believed, was the knowledge of how best to preserve the nutrition of the body and thus take advantage of Nature's wonderful power of recuperation in early life.

**The Diagnosis of Pneumonia and Empyema in Children, with an Analysis of 200 Cases.**—Dr. ALFRED HAND of Philadelphia, in this paper, referred first to certain differences in the physics of the child's chest as compared with the adult's, and called attention especially to the harsh character of the normal breath-sounds, the so-called "puerile" quality, and to the soft character of the bronchial breathing in the child, the latter resembling in intensity the normal bronchovesicular breathing in adults. The importance of the frequent examinations of the plain as well as of the doubtful cases was urged. A small or even large area of consolidation might give to bronchial breathing and increased vocal resonance, while palpation and percussion showed nothing, but sometimes all of the physical signs were negative when the diagnosis rested on fever, increased respiration rate above forty per minute, and leucocytosis, the latter serving to differentiate the sickness from typhoid fever. Lumbar puncture he believed might be necessary to exclude meningitis. The possibility of the development of empyema should always be borne in mind, as well as the possibility of the presence of pus in the

chest without causing fever, displacement of the apex-beat of the heart, absence of vocal fremitus and resonance, and bronchial breathing. Two hundred consecutive cases were analyzed with reference to age, sex, location of consolidation, maximum range of temperature, pulse and respiration, and termination by crisis, lysis, empyema, or death. An interesting feature was the greater tendency of pneumonia to affect the right lung. In the well-formed children the rapid breathing was dependent upon a toxic action on the central nervous system rather than a diminution of lung capacity by extensive consolidation.

Dr. J. P. Crozer Griffith of Philadelphia, who opened the discussion of the two papers, said that there was so much of Dr. Holt's paper with which he was in such thorough accord that he could but emphasize what was said and express his own views as corroborative of them. He believed that even a slight modification of the milk given the baby was a very important matter. He advocated the starvation treatment of acute indigestion, and in returning to the milk diet he would rather err on the side of returning too slowly than too promptly. It was his plan to put the choreic patients to bed for the rest and quieting of the nervous system. In the treatment of pneumonia he entirely agreed with Dr. Holt, believing that the object was not to cure the pneumonia, but to take care of the baby. Regarding the paper of Dr. Hand, he believed that the more experience one had with the diagnosis of pneumonia and empyema in children the easier many things became. Auscultation and percussion, in his opinion, played a minor part compared with the general symptomatology presented by the baby.

Dr. J. H. McKee of Philadelphia said that in the diagnosis of empyema the first essential was to be on the lookout for it, and the form of the empyema as well as its presence should be determined. In the differential diagnosis of pneumonia and empyema he considered the resistance offered to the pleximeter in percussion of great importance. Experimental puncture he thought was of value both diagnostically and prognostically.

**Acquired Hydrocephalus with Atrophic Bone Changes, Exophthalmos, and Polyuria.**—Dr. Thomas W. Kay of Scranton exhibited this case in a boy of seven years, the only child of healthy parents, who up to four years of age was himself healthy. He then had scarlatina, which was followed by discharge from the right ear, which still persisted. Three years afterward he had vertigo, and enlargement of the superior cervical and submaxillary glands occurred. Five or six months after the scarlatina the gums began to separate from the teeth, and this was followed by a gradual loss of teeth. At about the same time there was noticed a soft spot on the head where there seemed to be no bone. Eighteen months ago exophthalmos appeared, and the condition has been steadily growing worse, and was now so bad that the eyes had to be protected with a handkerchief, they being too prominent for the use of glasses. Polyuria was present; as much as 27 ounces of urine at a time was passed; the reaction was neutral, and sp. gr. 1.000 to 1.001. The lower jaw had lost its bone salts, and the resultant cartilaginous mass containing one incisor had been so deformed by the depressor muscles that the chin had disappeared. The child presented the most distressing picture imaginable, and was exhibited for diagnosis. No diagnosis, however, was suggested.

**The Adaptation of the Public to the Principle and Practice of the Prevention of Tuberculosis.**—Dr. Howard S. Anders of Philadelphia said that at the present time the prevention of tuberculosis was the largest, most important, and most urgent task concerning the public health. He contended that instruction of the public in the diligent and intelligent application of prophylactic measures against tuberculosis should not be an interminably slow process, and that the initiative need not be a game of waiting by the many upon the few, but must be the action of more with the willing cooperation of most of those who followed, and yet who made up the consistent solidarity of any community. There was, he said, sorely needed a general adaptation, especially by officials, representative bodies, landlords, and various large corporations to the doctrine that no conditions were socially or morally permissible which fostered the propagation of tuberculosis. The public adaptation to the doctrine of the communicability of tuberculosis he regarded of primary importance. Adaptation also called for the suppression of extremists, the sensational alarmist, and the irrational antagonist, and, between them, the fatalist. The sanatorium movement was particularly emphasized as the most far-reaching and efficient means of attacking tuberculosis. Public adaptation in the matter of the dust menace the author considered was hardly more than a threshold recognition, and he felt that much might be accomplished were the street dirt removed at night and the remaining dust kept down during the day by sprinkling. Dr. Anders believed that no better Federal adaptation to the movement could be consummated than the placing of a cabinet officer at Washington at the head of a Department of Public Health.

**The Diagnosis of Incipient Pulmonary Tuberculosis.**—Dr. George William Norris of Philadelphia read this paper, in which it was stated that "earlier diagnosis" was the constant cry of the sanatorium doctors. The diagnosis could not be based upon any one symptom or physical sign, but must be made in the light of the whole complex. Careful consideration of the anamnesis he believed of the greatest importance, and stated that by incipient tuberculosis was meant a slight initial lesion in the form of infiltration, limited to the ajex or a small part of one lobe, without tuberculous complications, and with slight or no constitutional symptoms (particularly gastric or intestinal disturbances or rapid loss of weight). Slight or no elevation of temperature or acceleration of the pulse at any time during the twenty-four hours. The expectoration was usually small in amount or absent. Tubercle bacilli might or might not be present. Dr. Norris attributed much importance to the careful inspection of the bared chest, and believed that enlargement of the bronchial or cervical lymph nodes should always be looked for, and the patient should be made to breathe properly before beginning the examination. Rapid pulse or slight evening rise of temperature, if persistent or unexplainable upon other grounds, he regarded as suggestive, especially if associated with loss of weight, diminished capacity for work, or cough. With the occurrence of any two of the last-named symptoms for a protracted period the physician should show cause why a diagnosis of tuberculosis should not be made. In the event of uncertainty, the patient should be treated as if he had the disease. The mere fact that the symptoms disappeared in the course of a few weeks or months was not regarded as proof that they were not caused by the tubercle bacillus.

**Sanatorium Treatment of Tuberculosis.**—Dr. George B. Kalb of Erie made a plea for the early diagnosis of the disease and for not depending on the microscopical examination of the sputum, and declared the modern treatment of the disease to be a tripod: (1) Open air, (2) forced feeding, and (3) graduated exercise. At the White Haven Sanatorium he stated that patients were classified upon admission as to involvement, on discharge as to results. There were, he said, four classes in each case: (1) Those with one lung without softening, (2) one lung with softening, (3) both lungs, and (4) with cavity formation. He gave an account of the plan of treatment of the disease and its complications, hygienic, dietetic, and medicinal, the daily life of the patient, and the influence of treatment on the patient's mind. Dr. Kalb advocated the establishment of three kinds of institutions: (1) For incipient cases, (2) for advanced cases, (3) for far advanced cases. By this means he believed that the curable would be cured and all kept from spreading contagion.

**Outdoor Life Versus Confinement in the Treatment of Bone Tuberculosis.**—Dr. H. Augustus Wilson of Philadelphia dealt with the results obtained in the treatment of

bone and joint tuberculosis in the open air at Atlantic City, Coney Island, Wellesley Hills, Blue Ridge Summit, Toronto, and elsewhere. Among the results of outdoor life it was noted: That osseous tuberculosis did not demand the varied atmospheric conditions necessary in the treatment of phthisis; that sleeping in tents or shacks with the temperature almost at zero F. had not been injurious; various operative and corrective measures required consideration in connection with outdoor life; there had been general improvement in the general health and strength, and no condition had been found too serious for betterment.

Dr. Ravenel of Philadelphia said that the physician should consider it his duty to instruct his patient, his clergyman, and his legislator in the truths concerning tuberculosis. He referred to the statement of a man at one time prominent in medical circles that it was an unwise thing to cure tuberculous patients, because they were never healthy. The opposite side of the question, which Dr. Ravenel considered much more important, was that unless an early diagnosis was made and the patient became a non-bacillary expectorating individual, the disease in a community could never be eradicated. To educate the people to this idea he considered as important as to cure the individual case. In treatment attention should be chiefly directed to rest, circulation, and digestion. He warned against the danger in forced feeding of the patient receiving impure milk.

Dr. Stahl of Philadelphia asked what method was employed by the readers of the papers in the emergency of hemorrhage.

Dr. Codman of Philadelphia referred to his practice of giving milk and eggs by having the yolks and whites beaten separately, and the whites poured upon the yolks, either sugar, salt, or a flavoring being added.

Dr. Miner of Wilkes-Barre referred to the administration of nitroglycerine and the restriction to a dry diet in hemorrhage.

Dr. Guthrie of Wilkes-Barre believed that local deposits of tuberculosis should, if possible, be removed.

Dr. Norris said that in the wards of the Phipps Institute in Philadelphia the routine treatment for hemorrhage was to put the patient to bed, apply an ice-bag to the chest, give a hypodermic injection of morphine, and assure the patient that there was no immediate danger and that a few weeks' feeding and rest would make up for the loss of blood. Ergot was never given.

Dr. Ravenel said that he varied the treatment of hemorrhage with the condition of the patient's blood pressure. He gave nitroglycerin as indicated. He thought it was not demonstrated that cutting off a liquid diet lowered blood pressure.

*(To be continued.)*

## THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

*Stated Meeting, June 12, 1905.*

The Vice-President, Dr. Ransford E. Van Gieson, in the Chair.

**Report of the Committee on the Death of Dr. John H. Hinton.**—This was read by Dr. Ransford E. Van Gieson, the chairman of the committee.

**The Radical Relief of Urinary Obstruction Due to Prostatic Hypertrophy.**—Dr. Lewis Stephen Pilcher read this paper. He stated that in operating for prostatic dysuria, the problem which the surgeon had to solve was not only thoroughly to remove the obstruction, but to do it without undue prolongation of manipulation, with as little loss of blood as possible, and with a minimum amount of injury to the urethra, bladder, rectum, and ejaculatory ducts, thereby lessening mortality and subsequent infirmities. At the present time three methods of attack presented themselves for choice: 1. Through the bladder by means of a suprapubic section. 2. By the perineum through a limited longitudinal median incision carried into the capsule of the prostate. In both of these methods enucleation of prostatic masses was effected by finger-tip dissection unaided by sight. 3. By the perineum through a free transversely curved incision, through which the prostate was fully exposed, followed by systematic incision into its substance, and subsequent enucleation largely under the guidance of the eye. Dr. Pilcher then discussed the indications governing the choice of operation in dealing with the various types of prostatic hypertrophy, and gave his conviction that, as a rule, for the best fulfillment of all the operative indications, there was necessary the free exposure of the gland by suitable perineal incision; the exposed gland should be brought down as far as possible into the superficial operative field by the use of suitable tractors, and the removal of the obstructing masses should be carefully and systematically effected under the guidance of the eye as much as possible. The speaker then described and illustrated the technique of the perineal operation that he favored. The steps of this operation, briefly, were as follows: 1. Placing the patient in an exaggerated lithotomy position. 2. Making a primary curved incision through the skin and superficial fascia, distant an inch to an inch and a half in front of the anus and extending from ischium to ischium. 3. The exposure of the rectourethral muscle. 4. Exposure of the prostate. 5. The downward traction of the prostate, with a suitable tractor. Personally, he had used with great satisfaction the model devised by Young. 6. Enucleation of the hypertrophied masses. 7. Insertion of bladder-drain, and closure of the wound.

Dr. Pilcher said that in the matter of the possibilities of radical relief of urinary obstruction due to prostatic hypertrophy, the question of the hour was not catheterization, nor castration, nor electrocaustic incision, but absolute, complete removal of the obstructing masses. Within the past fifteen years thousands of prostatectomies had been done, and the accumulated experience of those cases had demonstrated the following facts: 1. That removal of the whole or the greater part of an enlarged prostate was a feasible and reasonably safe operation. 2. That, with rare exceptions, complete healing of the operative wound took place, without permanent fistula or stricture. 3. That in the majority of cases, normal power to retain and to void urine was regained. 4. That these results had followed different methods of operative technique. 5. That the degeneration incident to advanced years and the presence of preexisting disease of the urinary tract, and the exhaustion produced by long suffering, loss of sleep, and the absorption of septic products prior to operation in many cases, added a special gravity to operative interference and entailed a certain hazard of mortality even in the hands of the most experienced, whatever the special method of operative technique employed. This mortality at present might be estimated at from five to ten per cent. 6. That, as the result of special conditions presented by particular cases, certain disabilities, more or less pronounced or continued, were not infrequent accompaniments or sequelæ of these operations. These, in the order of their frequency, were (*a*) sexual impotence; (*b*) epididymitis and orchitis; (*c*) partial urinary incontinence; (*d*) fistulæ. Nevertheless, even with these drawbacks, the fulfillment of the supreme indication, namely, the removal of the urinary obstruction, sufficed to obscure the presence of lesser evils.

**Perineal Prostatectomy by an Original Technique, with Illustrations.**—Dr. Parker Syms presented this communication. The method of operation was as follows: The patient, anesthetized with chloroform or ether, or with spinal cocainization, was placed on a short inclined plane, so as to be in a very extreme lithotomy position. A Syms staff was introduced into the bladder and a single incision made, opening the perineum down to the membranous urethra. The knife was then passed into the groove of the staff, and the membranous urethra opened throughout its length. A probe or curved director was passed to the groove of the sound, and thence into the bladder as a

guide; then the staff was removed and the index finger was pushed into and through the prostatic urethra, fully dilating it, into the neck of the bladder. The bladder was then thoroughly irrigated with sterile water, a rubber retractor introduced into the bladder and fully dilated and clamped. Sufficient traction was now made on it, the wound being dilated with the finger, the tissues were pushed aside, so that the sheath of the prostate was exposed, and a free vertical opening was made with the scissors. The prostate was then rapidly enucleated by the index finger. If the proper line of cleavage was found, this could be rapidly and almost bloodlessly accomplished. As soon as the prostate was removed, a large perineal drainage tube was introduced into the bladder through the prostatic urethra, and the wound and the space from which the prostate was removed were packed with iodoform gauze. This packing was made tight and firm in proportion to the amount of oozing encountered. The wound was then firmly sutured over the gauze, and the operation was complete. The patients were usually in bed within half an hour from the time the operation was commenced, and were up and about within forty-eight hours, the gauze packing being removed from twelve to twenty-four hours after the operation, and the drainage tube usually at the end of forty-eight hours. As to mortality, Dr. Syms said he had operated on thirty-four cases, with two deaths. In both of those instances, the patients were feeble old men, who apparently died as the result of the anesthetic.

Dr. Carl Beck said that while he regarded perineal prostatectomy, as described by Dr. Pilcher, as the ideal method, he did not think that some of the other methods of relieving the prostatic hypertrophy should be altogether condemned. For example, while the Bottini operation might be looked upon as an unsurgical procedure, still there were conditions under which it might be preferable to the ideal operation. Dr. Pilcher's statistics had shown that even in such skillful hands the perineal operation was not without danger to life in certain cases, and it was perhaps under just those conditions that the Bottini method might be preferable, even if it failed to effect a radical cure, and merely restored to the patient a moderate degree of health and comfort. Another factor to be considered was the personal equation. A man who did a certain operation frequently was almost certain to get better results from it than one who was less proficient.

Dr. Willy Meyer said he was decidedly opposed to the use of the catheter, which many physicians advised as soon as they were consulted by a patient whose bladder contained residual urine. It should be explained to those patients that in the end it was safer to submit to an operation than to use the catheter. The use of the catheter should only be advised in those comparatively rare cases where any operative interference was deemed unwise, and then only under the strictest aseptic precautions. Dr. Meyer said he did his first Bottini operation in 1897, and his result in that instance and in his seven succeeding cases was so satisfactory that between October, 1897, and October, 1902, he operated on fifty-nine patients by that method. Since then he had done the perineal operation in nine cases, the suprapubic in twenty-four, and the Bottini in eight, and his experience had led him to the conclusion that all three of these operations had a distinct place in dealing with hypertrophy of the prostate. The suprapubic operation he considered a most excellent one, and the more experience he had with it, the better he liked it. It was just as safe as the perineal operation, and could be done just as rapidly, especially in those cases where the gland was large and hard, and situated high up. He differed from those who held the view that this operation required special strength in the arm and fingers in order to enucleate the gland. The ease with which the gland could be enucleated simply depended upon the manner in which the manipulations were carried out. Perineal prostatectomy, which he had done in nine instances, was an excellent procedure in properly selected cases. There was still another class of cases in which any sort of a cutting operation was contraindicated, and it was among this class that he had seen patients not only improved, but absolutely cured by the Bottini method; patients who otherwise would have been condemned to the use of the catheter.

Dr. Eugene Fuller said that while he favored the suprapubic operation, which he had done about 250 times, he was inclined to agree with Dr. Meyer that one method was not suitable to all cases. He had done the perineal operation in 80 cases, following essentially the technique of Goodfellow. He did not make as large an incision as Dr. Syms, and made his cut upwards instead of downwards. He favored a small incision, as it would be less apt to result in a fistula than a large one. He did not think the suprapubic operation was more dangerous to life than the perineal. His own mortality by the former method for the past two years was four per cent. in his private cases, and about five and a half per cent. in his hospital cases, where many of the patients were in very poor condition. In dealing with a case where the prostatic retention had existed for a long time, where the bladder was in a succulent condition and would require long-continued drainage, Dr. Fuller thought it would be a mistake to resort to a perineal operation. Under those circumstances, the mere removal of the prostate was of secondary importance; to secure effectual drainage was the main factor, and this could best be done through a suprapubic incision. Long-continued drainage could not be carried on through the perineum. Another objection to the perineal route was that in cases where much dissection was necessary there was danger of injury to the rectal wall. He had never yet in his prostatectomy work torn the rectum or given rise to a vesicorectal fistula. Theoretically, it appeared very easy to enucleate the prostate, but in some instances it was very difficult, and in malignant cases it might even be impossible. As to the question of sterility, he could recall a number of instances where patients who had been previously impotent for a number of years were restored to potency by the operation. In advanced cases, of course, when the sexual power had been lost for many years, the outlook was not very promising, but in certain instances where the hypertrophied prostate pressed on the ejaculatory ducts and obstructed the act of ejaculation, the sexual power might be restored by prostatectomy. Dr. Fuller said that in most of his work upon the prostate he depended largely upon the sense of touch rather than the sense of sight.

Dr. James Pedersen said his experience in this field had been limited chiefly to the Bottini operation and to perineal prostatectomy. In selecting cases for the Bottini method, he was largely guided by the rules so well laid down by Dr. Meyer. His results with the perineal method had been very satisfactory, and he was often surprised by the facility and ease with which the enlarged gland could be reached and manipulated through such an incision. The tractor he had usually employed was that devised by Dr. Young, but there were cases in which that instrument could not be introduced, and in those instances he had found the old-style placental forceps an excellent substitute for the purpose of seizing and bringing down the enlarged lobes. Much of the success of prostatectomy, Dr. Pedersen said, depended on the after-treatment, the important factors of which were: 1. Short period of drainage, which included the early removal of the packing from the wound. 2. Short period of confinement in bed. 3. Free diuresis. 4. Occasional catharsis.

**"League of Pitiful Deliverance."**—A society having this title exists in Siberia. The object of the society is the killing of the aged and infirm relatives of the members of the order to put them out of pain. The death of such persons is decreed by a secret tribunal. The existence of the society was revealed by a woman, a sufferer from rheumatism, who objected to the death sentence and informed the police, thereby causing the arrest and trial of three brothers for conspiracy to murder.—*American Medicine.*

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 30, 1905:

| | Cases | Deaths |
|---|---|---|
| Measles | 73 | 2 |
| Diphtheria and Croup | 171 | 18 |
| Scarlet Fever | 51 | 5 |
| Smallpox | .... | ..... |
| Chickenpox | 23 | ..... |
| Tuberculosis | 380 | 146 |
| Typhoid Fever | 113 | 24 |
| Cerebrospinal Meningitis | 2 | 5 |
| Typhus Fever | ..... | ..... |
| Yellow Fever | ..... | ..... |
| Cholera | ..... | ..... |
| Totals | 813 | 200 |

**The Leucocytes in Whooping-Cough.**—C. G. Grulee and D. B. Phemister have made examinations of the blood in fifteen cases of whooping-cough, and give us the following conclusions; (1) Leucocytosis is present in all stages of whooping-cough. (2) The number of leucocytes increases with the increased frequency of the paroxysms and becomes less as the paroxysms become less frequent and severe. (3) The mononuclear leucocytes are relatively increased in all stages of the disease. (4) In the paroxysmal stage the lymphocytosis was due largely to the large lymphocytes. In the catarrhal stage in some cases the small mononuclears were in excess. These results correspond with the results of other observers. The normal blood during infancy and childhood gives at birth 17,600 with 75 per cent. polymorphonuclear leucocytes; within forty eight hours lymphocytes begin to increase and polymorphonuclears to decrease until they reach 36 per cent., while the small lymphocytes are 45 per cent., large 1 per cent., transitional 18 per cent., and eosinopiles 1-3 per cent.—*Archives of Pediatrics.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the period from September 16 to 23, 1905:

SMALLPOX—UNITED STATES.

### THE OFFICE TREATMENT OF DISEASES OF THE RECTUM, WITH A DESCRIPTION OF SOME NEW METHODS.

By CHARLES B. KELSEY, M.D.,

NEW YORK.

When one considers the vast number of people who pass a great part of their adult lives suffering the pain and annoyance caused by some trouble with the rectum, rather than undergo even the simplest surgical operation attended by the horrors of anesthesia, hospital, and the knife, any effort at cure or relief unattended by these conditions is certainly commendable.

It may be that these horrors are purely imaginary, that anesthesia and operation are even in fact much less painful and more efficient than any other form of treatment; but that makes no difference. The mass of our patients may be timorous, or, to our minds, even silly on these points, but these are the people we are called upon to relieve; and if there be any means of doing this consistent with the safe and honest practice of surgery, they are entitled to them.

It is but fair, however, that the exact conditions should be stated beforehand, and these may in many cases be put to the patient about as follows: "If you wish to be radically cured in the shortest time and with the least suffering you will put aside your imaginary fears, take a little laughing-gas or ether, and be operated upon. If you prefer not to do this, but to spend more time, and possibly suffer more pain in the end, much may still be done, and in many cases a complete cure may be attained by other means." Many patients will choose the former after such an explanation, and many the latter, but the choice rests with them.

As to what these other methods are the profession may be interested to know exactly what, in my own experience, I have found it possible to accomplish in my own specialty, what it is best to attempt, what to avoid; especially as we all know the question to be surrounded by much self-advertising quackery.

I will only add that my efforts began about twenty years ago with the injection of carbolic acid into hemorrhoids, which I at first strongly advocated and subsequently as publicly condemned; and some of my older friends and confrères may remember the amount of criticism I received because having thought a thing was good and said so, I afterwards discovered it to be dangerous, and said so. My experiments have gone on steadily ever since (though I may have been more cautious about saying things were good in the fear of having to retract); they have covered every method of which I have heard which appeared in my surgical sense as safe and efficient, and some rather original ones; and to the results the profession is welcome. The intermediate steps are hardly worth recording.

Before the discovery of cocaine the efforts of the workers in this line were confined almost entirely to the treatment of hemorrhoids by injections of carbolic acid and other drugs. This could be accomplished either through a speculum in non-prolapsing cases, or without any speculum in cases that protruded, and was not attended by any great pain at the time. As to its value the profession has certainly had time to decide, and my own views are well known. Occasionally it is still heard from. Personally I abandoned it many years ago, and after an interval in which, returning to first principles, all my cases were treated by the safer method of the clamp and cautery, began on entirely different lines.

The first great advance was the appreciation of the value of cocaine, and one of its greatest benefits was that by injecting a solution of it, not into the rectal tissues, but into the rectal cavity, and leaving it for a time, a speculum or the finger could be used and a diagnosis made, and possibly even a cure effected, in a whole group of cases which had previously been absolutely unapproachable, except under profound general anesthesia, because of the pain caused by an attempt at examination. Naturally this practice has been permanently adopted, except that when eucaine became known cocaine was abandoned, the former having equal anestheic effect with much less constitutional disturbance.

While upon this point of local anesthesia I may say that the recent exploiting of simple water as a local anesthetic has not appealed to me. It is certainly not new, for it has been a scientific curiosity for years; but the practical advantage of injecting an ounce of water into the tissues to secure an effect which can as well be gained by ten drops of a very weak and absolutely safe solution of eucaine is not manifest, while the disadvantages are obvious. Moreover, eucaine in many cases can be efficiently applied on a piece of cotton allowed to rest on the spot and need not be injected into the tissues at all to produce full anesthesia.

Having thus touched upon local anesthesia as the *sine qua non* of these methods, and a substitute for laughing-gas and ether, let me add that though with it much can be done, by it the sphincters cannot be stretched without pain; and this is very definite and positive limitation to its usefulness, through which a very large proportion of the most delicate and difficult surgery of the part is still left dependent upon general anesthesia. By it, as I have said, a speculum may be used in cases otherwise impossible; but by it complete exploration of the rectum through dilated sphincters—the only way in which complete exploration can be done—cannot be effected. Cannot is a strong expression, and though it conveys my meaning may be modified to this extent. If dilatation be attempted with cocaine or eucaine the numerous injections will be very painful and the constitutional effects of the drug marked. If attempted with water, the distension will be still more painful, and there may be sloughing of the tissues as a result, for this has been known. In neither case will there be satisfactory anesthesia.

**Fissure.**—There are two distinctly recognized ways of treating fissure of the anus—in fact, three. I say three because the third is to treat an ulcer here exactly as elsewhere in the body—not by any sort of surgical operation, but by simple stimulating dressings intended to induce a sluggish ulcer to granulate and heal. It is wonderful how many ulcers here can be made to heal exactly as they would heal elsewhere, by applications, not of the solid stick of nitrate of silver, but of charpie covered with ungt. hydrargyri ammoniati; balsam of Peru; charpie alone; or any other mildly stimulating application.

But, outside of this, a fissure may be cured by either stretching the sphincter, and thus rupturing its muscular fibers, or by incising the sphincter, and thus putting to rest its muscular fibers, which underlie the ulcer. Both procedures cure the ulcer by inhibiting the action of the muscle upon which it rests. Stretching can only be done under general anesthesia carried to its limit. Incising can be done with ten minims of a weak eucaine solution placed hypodermically under the fissure. Provided there be no complication such as a polyp or hemorrhoid hanging into the fissure and preventing its healing, either method will be equally successful, and the hypodermic anesthesia appeals most strongly to the patient, in that it avoids a so-called "surgical operation."

Now, I suppose it is not the least exaggeration to say that on an average of once a month for years back I have been appealed to in cases like the following. Patients in the upper walks of life, generally women, but sometimes men, have come to me, saying, "Doctor, I have a fissure. I am suffering intense pain. Dr. —— (mentioning someone of my most respected confrères) has examined me and says it is necessary for me to take ether, to have the muscle stretched. Can you do anything for me without this operation?" Their physical suffering is very real; their mental suffering is purely nonsense; that is granted. And yet when I say, "That may be possible," and when, after examination, I bathe that fissure in strong eucaine, or inject weaker eucaine under it till all sensation is abolished, and incise it freely, and cure results, these patients are very grateful.

This is but an example of the whole question under discussion, and the only question remaining is whether this treatment is as efficient as general anesthesia and stretching. Frankly, I say, not quite. Fissure in some cases is secondary to other affections, such as polypus or hemorrhoids. With general anesthesia these causative affections will probably be discovered and removed in the act of stretching the sphincter to cure the fissure. With local anesthesia they are very likely to be overlooked. Without any carefully prepared statistics to refer to I should say that the proportion of cures by local anesthesia to that by general anesthesia was as ninety-five to a hundred.

It is amazing what an operation a patient will submit to as long as you don't call it an "operation," but just simply do it with local instead of general anesthesia, and without hospital or trained nurse. A patient will be operated upon in the office, go home and stay abed a fortnight, get well and go about again, and always aver that he was cured without an operation simply because he did not take ether, whereas the surgical procedure was exactly the same under local anesthesia that it would have been with ether, and the confinement and after teatment the same.

But the ether is to most patients the dreaded element of an operation, and it is this I am pointing out how to avoid it.

Considering now another of the most common and annoying affections of this part, in which local may often be substituted for general anesthesia, we will say a few words about

**Pruritus Ani.**—In many cases of pruritus it is necessary to use strong measures to reduce the long-standing hypertrophy of the skin, before the itching can be relieved, and the best of all these is the actual cautery where salicylic acid in strong solution has failed. Now the actual cautery (galvanic or Paquelin) may be applied once for all under general anesthesia (which constitutes an "operation"), or it may be applied at different points at successive intervals under local anesthesia—which constitutes the cure "without operation." This is my own favorite method, and by it, combined with all the knowledge of general medicine, surgey, dermatology, and pharmacology I have been able to acquire in a lifetime of practice, I accomplish what results I am able to secure in this most complicated and intractable disease. There isn't a vestige of a secret about it. The rule is, destroy the old hypertrophy when necessary, and then go on and treat the skin disease—and destroy the old hypertrophy under either local or general anesthesia, as you choose, or with the actual cautery or chemical applications, as you choose. The man who can cure an obstinate case of pruritus with or without operation is one whose knowledge of general medicine and three or four specialties is worthy of a good deal of respect. Personally, I have found that local anesthesia and gradual work were more efficient than any attempt to do all of the work at one sitting by an operation, for the simple reason that after what the patient considers an operation he expects to be cured at once, whereas the destruction of the skin is only one step toward cure and only a part of a general course of treatment which generally includes many other things.

**Fistula.**—Fistula is such a hydra-headed disease I hesitate to speak of it in this connection. I have cured fistulæ (several of them) by colostomy and subsequently closed the artificial anus and left my patient well. I have cut, in my early days, several very extensive fistulæ and lost my patient by putting him through a more extensive capital surgical operation than the system could withstand. I have just discharged as cured a private patient who had been under treatment for three years by one of our most respected general surgeons in New York and pronounced by him incurable; and this was only accomplished after eighteen months of continuous daily supervision and *five* etherizations. This was a tubercular case, where every surrounding influence was in my favor.

After this prelude we approach the question of the cure of fistula "without operation." Such a thing is possible, but very rarely. One of the most remarkable instances I have ever seen was a tract running several inches directly upward into the ischiorectal fossa which had been cut so often the patient would not consider any further surgery, and consulted me simply to know if anything could be done without cutting. Almost without expectation of accomplishing anything strong tincture of iodine was twice injected, so as to distend the tract, and the patient, to my surprise, was cured. Other cases I have cured along this same line—curettage, stimulation, drainage—but in the vast majority the attempt has ended in failure, and it should not be undertaken except on this understanding and at the patient's pecuniary risk.

When we get to the point of laying the tract open or to what generally constitutes the treatment, we have to consider the choice between local and gen-

eral anesthesia—office or hospital. Some, and those the simplest, can be done in the office perfectly well; and this being the case, it is just as easy to do all of it at one sitting as to do it piecemeal and pretend it is not an operation. But only the simplest can be cured in this way, and the failures result from cutting a branching sinus as though it were only a straight one, and not detecting the error until failure to cure leads to better surgery.

As a general rule the man who puts his patients under general anesthesia, sits down quietly and dissects out his fistula, will succeed in curing where the one who attempts this with local anesthesia will fail. But so much depends upon the individual case that it is impossible to generalize; only without general anesthesia it is very often impossible to be sure of the nature and extent of the case.

Experience will bring wisdom, and also teach great caution in promising results; and it may be a consolation to some of my readers to know that within the past year I have operated on a patient in my office, failed utterly to find the tract, and sent him home as cured of what I thought must be only one of a succession of small furuncles, only to have him return in a few weeks with another. This time, being convinced there must be a fistula, I took every precaution, including etherization and hospital, found a little sinus about an inch long, and sent him home again as positively cured. But he isn't. He writes me he is exactly as he was when I "cured him first time." Something unusual we evidently have come across, and though I have no idea what it is, I still hope for a chance to discover, and to cure the man.

**Hemorrhoids.**—After abandoning the treatment of hemorrhoids by injection years ago I began a systematic search for some method which should accomplish the same purpose; viz., a cure without general anesthesia or confinement to the house, and which should be free from the dangers inherent in carbolic acid. For years then I had made it the rule in my clamp and cautery operations, after using the clamp in two or three spots, to treat any remaining small tumors which seemed possible sources of future trouble by puncturing into them with the tip of the Paquelin instrument, thus destroying them without the risk of too great contraction which always attends the too free use of the clamp, and this is still my practice.

The method is similar to that often relied upon in France as a recognized procedure for the cure of all hemorrhoids, and is there known as punctate cauterization. Gradually this method became of more general scope in my own work until I began to apply it to more severe cases, to use it in my office with local anesthesia instead of in hospital, and to use a galvano cautery instead of the Paquelin, as more convenient.

Whether this treatment of my own has led to the now common and utterly senseless use of the constant or interrupted current around and through these parts, and to the so-called method of curing hemorrhoids by "absorption by electricity" I know not; but this so-called method of cure has become quite common since I began the use of this method. There is no "electrical absorption" and no electrolysis in my method. It is simply the punctate cauterization with a needle rendered hot by electricity, of a hemorrhoid which has previously been made insensible to pain by the injection of a few drops of a weak solution of eucaine; and the object is to cause destruction and cicatrization, not absorption.

The source of electricity is the street current and the needles used are those to be found in every instrument shop for accomplishing this purpose in growths and ulcerations in the nose and throat. It was, in fact, to the work done by my friends in these specialties that I was indebted for many of my ideas, added to my memory of the way one of our best surgeons of the past generation used to cure cases of birthmark—by holding an ordinary shoemaker's awl to an alcohol lamp until it became hot, and then plunging it into half a dozen points of the tumor, thus shutting off its blood supply and leaving only a white scar.

The question in my mind was if this could be done with such a vascular tumor, why not with hemorrhoids, and the result proved that it was perfectly possible.

The principle has been stated. The technique where the tumor can be made to protrude is very simple, in other cases often exceedingly difficult; for a speculum must be held with one hand while the applications of eucaine and cautery are made with the other. And yet it is to exactly this class of cases that the method is best adapted, for a hemorrhoid which can be brought down and seized with forceps may be also tied off under eucaine; but one which cannot be brought down cannot be properly tied off or clamped and cauterized without dilatation of the sphincters; and to do this under local anesthesia properly and efficiently is not possible. Neither the ligature or clamp operations are done through a speculum, but only after dilatation. This one is done without dilatation and by means of a speculum, and under eucaine in the office; and in this difference consists its advantage and its indication.

But little more need be said as to the technique. The speculum used is the one generally sold under my name; the hypodermic an ordinary one with side handles; the hypodermic needles fine and rather long; the platinum cautery tips also fine, and straight or curved, as needed. Ten or fifteen minims of a weak eucaine solution are first deposited in the most prominent part of the tumor which will turn white from the distension of the fluid, and after a delay of a few minutes, to allow this to take effect, the platinum wire, heated to the point of redness, is plunged fairly into the substance of the tumor. One, or at most two, applications are enough at one time, and these should not be made oftener than twice a week at first. After four or five of these applications, if pain or soreness is complained of, it is well to stop treatment for a week, to allow of healing. The time consumed by the method in an ordinary case is usually about three months, although it can be done in much less. During that time, although there will be some pain for a day or two after the treatment, the patient is not expected to be confined to the house or unable to attend to his ordinary duties. Accidents, such as abscesses or hemorrhage, I have never met with, although when used near the mucocutaneous junction I have seen an edematous swelling appear at the nearest point of the skin within an hour, only to subside spontaneously in a day or two. This is the only thing in the nature of a complication I have ever observed, and this will not occur when the applications are fairly above the sphincters.

As to permanency of result, I now have patients, treated in this way ten years ago whose hemorrhoids, prolapsing and bleeding, and requiring replacement when they came to me, have never returned, and my experience with it in all classes of cases has been rather extensive.

It should not be necessary to say that the method is not adapted to tags of skin which can be snipped off with scissors.

It may be asked what advantages has all this over the injection method. Chiefly, to my mind, these:

In this there is no irritating fluid deposited in the middle of a vascular tumor, and left to do its work, with no escape for the products of suppuration except what nature may provide, sometimes at a considerable distance; but in this case there is an antiseptic puncture, left open necessarily, to allow for natural drainage.

In the one case there is a distinctly circumscribed antiseptic surgical traumatism, limited in extent by the will and skill of the operator. In the other a focus of inflammation is deposited deep in the tissues to take care of itself.

My own preference for this treatment over that by injection can be stated in fewer words. After ten years of steady trial this one has never caused me a moment's uneasiness, or even a cutaneous abscess. The other has caused extensive suppuration in my own hands, and death in the hands of others who have been more unfortunate through no blame of their own.

And yet I have been slow in publishing this method, for I am convinced that, should it become popular, there will at once be a chapter of accidents resulting from its improper use by unskilled hands. The precautions I have always taken will be neglected, the description of technique will be disregarded, modifications and improvements (?) will be invented; and for this reason I have preferred to leave the unskillful to their harmless method of causing "absorption by electricity." It is not now recommended for universal adoption, or even put forward as an improvement upon the clamp or ligature operations. Rather, it is a description of what I have personally been able to accomplish in the way of curing the timid sufferer, who had rather suffer on than be cured by an operation involving ether and the knife.

Either the ligature or the clamp operation, preferably the former, may, in selected cases in which no stretching the sphincter is necessary, because the tumors protrude spontaneously, be performed under local instead of general anesthesia, and the results as to pain and confinement to the house will be exactly the same. Also if patient and surgeon prefer they can be done in the doctor's office and the patient sent home in a cab with an opium suppository in his rectum, instead of comfortably in his own bed. I do not do my own operating of this kind in my office either with local or general anesthesia, but that may be merely a matter of preference; but I have often found a distinct advantage in using eucaine instead of general anesthesia, especially in old or very nervous and timid patients. But again I must insist, even at the expense of being wearisome, that this is only in cases where the tumors can easily be brought outside the anus and the surgeon's work is all before him. That a case of internal hemorrhoids, bleeding and painful and demanding operation, but never protruding to any extent, can be satisfactorily operated upon either by ligature or clamp, as such cases should be operated upon under any form of local anesthesia I do not admit. I have earnestly tried, to the disgust of my patient, my trained nurses, and myself. The very first step in such a case is the free dilatation of the sphincters. Then comes the dissection of the tumor from its base of attachment, and then the clamp or the ligature to its pedicle. It is manifest to any surgeon that this can only be done cleanly and satisfactorily under general anesthesia.

There is much more of the minor surgery of the rectum which can be facilitated by the use of local anesthesia. For example, the largest polypus I have ever encountered, one fully three inches long with a fleshy pedicle, an inch in diameter, was removed with perfect ease in this way. Also, in the routine treatment of various ulcerations much suffering from the introduction of the speculum may be avoided; and sluggish sores may be curetted and cauterized, and many slight operations done by this means which, but for it, could only be done under ether. So that I have come to keep a solution constantly ready for routine office work, for hypodermic use, for application on cotton, for injection into the rectal cavity previous to the introduction of a speculum; and by it as every oculist or laryngologist knows, much suffering may be saved, and much etherization and hospital work avoided.

But this is about the limit, and we have not yet reached the point where all the surgery of the rectum, including partial or complete extirpation, is best done in one's office under local anesthesia.

As I wrote ten years ago, "A very large proportion of all cases of piles, fissures, superficial ulcers, and pruritus, and a certain proportion of abscesses and fistulæ may be radically cured in one's office without resorting to ether or confinement to bed." As to how this may best be done, I have here endeavored to show, as well as to point out in what class of cases it is best adapted.

More than ten years ago my dear friend and associate, Dr. Gibbs—the first officer shot in the Spanish War—after two or three years' experience in my office, said, one day: "The fact is, nine-tenths of this rectal surgery is minor surgery, and could be done in your office just as well as in hospital." His statement was a little exaggerated. For nine-tenths I should substitute one-half, and yet there is no question that too much fuss has been made over the whole business. The idea of sending a delicate woman to a hospital, giving her ether, and having a trained nurse; or of getting in a trained nurse to her own house, and having an expert anesthetizer come and give her ether to accomplish the cure of a simple fissure, is a little ridiculous. The disproportion between the means used and the end to be accomplished is too great. The secret of success lies in knowing in what case to try one method, and in what the other. This only experience can teach. Occasionally, after years of work along this line, I slip myself; and both patient and I are glad to get the former safely in bed in hospital, have him fully under ether, and have him cured in the easiest possible way for me.

But I am not considering this question from the standpoint of what is easiest for me. Perhaps, if I were, I should put them all in hospital.

My point of view has been simply this—what can be done for the timid patient who objects to hospital, to ether, and to operation?

The result of many years of work along this line has been very briefly stated. As I said years ago, in a little pamphlet on this subject, it embodies no new principle; no secret remedy. It is simply the systematic adaptation of methods known to all my confrères, carried perhaps a little further than they have usually been carried, to the treatment of a certain class of affections of a certain part of the economy.

18 East Twenty-ninth Street.

**A Finger Ring for Ligatures.**—The vicissitudes to which the ligature or suture material is subjected in its course from the instrument table to the hand of the operator has induced v. Bramann to invent a device by which all the handling to which the material is ordinarily exposed be eliminated. The small metal reel upon which the silk or catgut is sterilized and preserved is made so that it may be enclosed in a perforated metal capsule and affixed to a ring slipped over one of the fingers of the operator's left hand. He thus has an abundant supply of material constantly at hand.—*Zentralblatt für Chirurgie*

# THE VAPOR METHOD OF ANESTHESIA.*

By JAMES TAYLOE GWATHMEY, M.D.,

NEW YORK.

In 1847, over half a century ago, Sir James Y. Simpson introduced chloroform as an anesthetic. Putting an unmeasured quantity on a handkerchief,—thus administering it, as he said, "powerfully and speedily,"— it is not surprising that in less than a year the first victim of chloroform, Hannah Greener, died from the effects of the concentrated vapor, as thus administered, Dr. Simpson being the anesthetist. As the death rate increased, he modified his instructions so as to give it "drop by drop." Dr. Snow was the first to recognize the very great danger of giving as powerful a drug as chloroform by the drop method, as this always means, however carefully given, an unknown percentage of the vapor inhaled, consequently an irregular form of anesthesia at the best.

Clover and Paul Bert, both original investigators, agreed with Snow as to the vapor method, and constructed inhalers accordingly. Junker's inhaler (Fig. 1) was the one universally used in Great

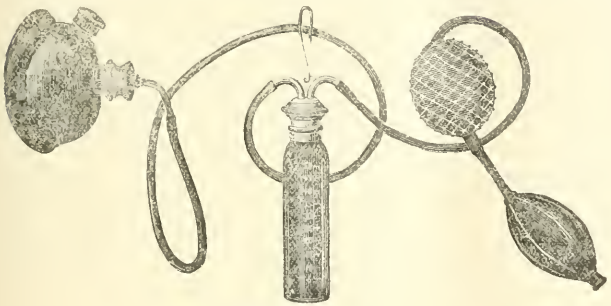

Fig. 1.—Junker's apparatus.

Britain until 1904. The great objection to Junker's inhaler is the closed mask (with valves) commonly used with it. This mask is not large enough to contain sufficient vapor for a full inspiration, thus throwing a needless strain upon both the respiratory and circulatory centers. This method was considered absolutely safe, but deaths have been recorded. These deaths were due, in my opinion, not so much to the chloroform vapor as to the faulty construction of this small, closed mask with valves, which compels the patient at times to attempt to breathe from a vacuum.

Fig. 2.—The Harcourt inhaler.

For those who prefer the closed method, a large, thin rubber bag, placed immediately behind the inhaler, removes this element of danger. The bag should always be two-thirds inflated, thus insuring a plentiful supply of vapor at all times. The amount and cost of the anesthetic are thus reduced to a minimum, and this fact would appeal to those to whom these items would be of the greatest consideration.

The Harcourt inhaler (Fig. 2), which has been endorsed by the last special chloroform committee appointed by the British Medical Association, meets all the requirements for a definite dosage of a known percentage of chloroform vapor. It gives a maximum two per cent. chloroform vapor, which has been found sufficient to induce anesthesia in the majority of cases. After surgical anesthesia has been reached, it is satisfactorily maintained by a one per cent. vapor or a fractional part thereof.

The principal objection to this last-named inhaler is that it is necessary to use a closed mask with valves. Valves, however well made, mean increased effort at breathing. Then, again, this inhaler can be used for chloroform only. If, for any reason, a change should be indicated, it would be necessary to change the inhaler and the mode of administration with a possible interruption of the operation. From all accounts, it unquestionably gives a perfectly even and safe anesthesia.

Dr. Braun of Leipzic modified Junker inhaler so that either chloroform or ether alone, or any combination of the two drugs, may be given. (See Fig. 3.) A metal mask, without valves but with a small opening in the top to insure the supply of air, comes with the apparatus. Although this mask is an improvement over Junker's, yet, on trying it myself, I found the sensation so unpleasant that I immediately discarded it, and have, since that time, always used one of my own, a modification of Hewitt's (Fig. 4). This consists of an anatomically correct, fitting face piece, the rim of which is hollow and perforated with small holes around the inner margin so as to allow the vapor to escape. In all other respects it is identical with a folding Esmarch mask. This is covered with two to four layers of gauze, over which

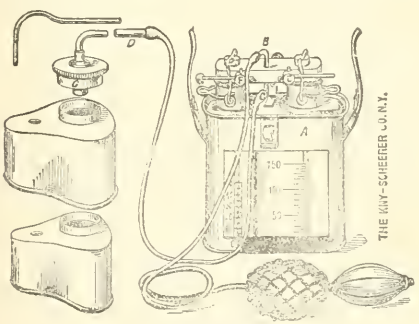

Fig. 3.—The Braun inhaler.

*Read at a meeting of the Medical Society of the County of New York, September 25, 1905.

is placed a piece of oiled silk or rubber tissue. A small opening, the size of a ten-cent piece, is cut in the middle of this gauze so that, during the induction period, a few drops of chloroform may be added, as it sometimes necessary with vigorous alcoholics.

There are no valves, consequently there is no rebreathing, no unnatural nor strained breathing at any time. I have used this mask in connection with the Braun apparatus more than two hundred times,

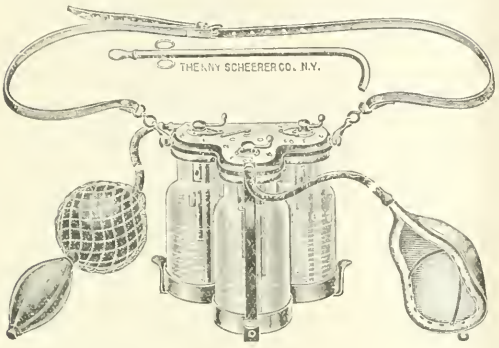

Fig. 4.—The Gwathmey vapor inhaler.

and on each occasion with an increased degree of satisfaction to myself. Dr. Braun's idea is to give a continual anesthesis by means of a highly attenuated ether vapor, to which, from time to time, chloroform is added, according to requirements. He thus secures the advantages of both agents, and discards their disadvantages. He adds only small quantities of chloroform, when the ether vapor is insufficient to produce the desired effects. When not using oxygen, I generally follow this method with my apparatus. The Braun apparatus is simple and easy to operate, and has decided advantages over the Harcourt inhaler. But the principal, and greatest, objection to these, and to all other inhalers up to this time, is that the air or oxygen cannot be increased or decreased without at the same time increasing or decreasing the anesthetic vapor. After much thought and a great amount of experimental work, I have succeeded, with the cooperation of the Kny-Scheerer Company, in combining the good features of the Braun and Harcourt inhalers in such a way that the result is a more perfect instrument than any yet produced (Fig. 4).

First of all, I have three six-ounce bottles in each of which there are four tubes, varying in length from one that reaches the bottom of the bottle to one that penetrates only the stopper. These tubes represent four degrees of vapor strength, the longest, No. 4, with the mask just described, has an estimated 1 per cent. vapor strength; the shortest, No. 1, representing a very attenuated vapor strength, 0.1 per cent. In addition to these degrees, by simply turning a small lever, without removing the mask, the patient gets pure air or oxygen (Fig. 5). With Junker's inhaler, if an estimated four per cent. vapor was obtained on full compression of the hand bulb, a very slight compression producing a one-half per cent. vapor, all of the vapors passing through the one tube that reached to the bottom of the bottle. If, then, with its one tube Junker's inhaler has five different vapor strengths, it will readily be seen that the new inhaler has four times as many or twenty varying degrees for each bottle.

The percentage vapor varies, then, according to the depth or amount, and also to the temperature, of the liquid, the size of the hand bulb, and the pressure with which the air or oxygen is forced through the tubes, either by the hand bellows or from the oxygen tank. It also varies with the tube through which it is passing, the longest tube representing, with the mask, one per cent., the shortest, a fractional, or one-tenth per cent. vapor. As the mask is not air tight, nor arranged so that the vapor can be compressed, there is no possible danger of ever getting more than this amount, although it is possible to lighten the anesthetic to any degree desired.

If the patient is a strong, vigorous man, or an alcoholic, the longest tube is used to get him completely under; then the stop cock is turned to the second longest, or No. 3. If the lid reflex is still sluggish, the lever may be turned to No. 2, and then to the shortest, or No. 1. If, now, this reflex gets too active, try the second length, or No. 2 tube. By thus working up and down from the shortest to the longest tube, and by also varying the pressure, the patient can be kept between an active lid or swallowing reflex, on the one hand, and a very dull lid reflex on the other. If the patient is an infant or is very weak, only the shortest tube is to be used from the beginning.

In order to determine accurately the varying percentages of vapor passing through the tubes, a number of interesting experiments were conducted as follows: By means of water pressure, a measured amount of air, dried by passing through sulphuric acid and calcium chloride, was forced through the bottle containing the chloroform. The difference in weight of the chloroform bottle before and after the passage

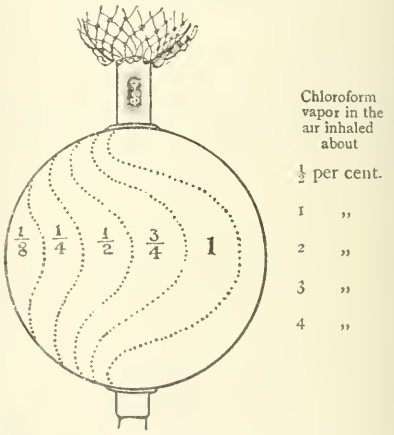

Fig. 5.—Showing amount of chloroform expressed; one-eighth compression giving one-half per cent.; full compression (1) giving a four per cent. vapor.

of the air through it gives the weight of the chloroform taken up by the air. A given weight of chloroform may be expressed in terms of volume by application of Avogadro's hypothesis. According to this, equal volumes of all gases at the same pressure and temperature contain an equal number of molecules. Conversely, a molecule of any gas has the same volume as a molecule of any other gas at the same pressure and temperature. As it has been determined that 32 G. of oxygen have a volume of

22,400 c.c., 119.5 G. of chloroform,—containing the same number of molecules as 32 G. of oxygen,—must also have a volume of 22,400 c.c. The calculation of the chloroform taken up by the air passing through it is 119.5 : 22,400 :: x : y, x being the loss of weight in the chloroform bottle, and y the volume of this weight of chloroform. And further, since the amount of air which has been passed through the chloroform is known (this may be called z), the percentage of chloroform in the mixture becomes $\frac{y}{y+z}$

In the determinations made, the air was driven through the chloroform for one-half hour at practically the same rate as when inducing anesthesia. The room temperature was about 65° F. With the lowest tube the following figures were obtained: Loss of weight in chloroform bottle, 15.57 G. Volume of air used in one-half hour, 10,900 c.c. The equation thus becomes 119.5 : 22,400 :: 15.57 : y. Hence y, or the volume of chloroform vapor taken up by the air = 2,918.5 c.c. This gives a percentage of $\frac{2,918.5}{2,918.5 + 10,900}$, or 20 per cent. The third lowest tube also gave a percentage of 20; the second, 10; and the top tube, 2.7 per cent. Similar experiments with the Junker bottle gave a percentage of 14.5. The tube here penetrates as deeply into the chloroform as in the other apparatus, but the surface area of the fluid is much less, and so allows of less evaporation. This accounts for the lower percentage.

These percentages, of course are for the chloroform in the mixture of chloroform and air as it comes directly from the bottle. The percentage actually inspired would be very much smaller. This latter can be only roughly estimated. A normal person breathes in about 500 c.c. of air in one inspiration. With 18 respirations to the minute, this would be equivalent to 9,000 c.c. per minute, or 270,000 in one-half hour. Since, in the experiments described, when an amount of air is driven through the lowest tube, at the rate ordinarily used in anesthesia, 2,918.5 c.c. of chloroform vapor comes to the mask in 30 minutes, the percentage of chloroform in the air inspired during this time would be 2,918.5 ÷ 270,000, or about 1 per cent. This calculation is undoubtedly too low, however, since the diminution in the rate and depth of breathing during anesthesia, and the accumulation of chloroform in the respiratory passages, would tend very materially to increase the percentage.

To repeat, the following are the tabulated results of the experiments as described: In the mixture coming directly from the tubes, the lowest tube gave 20.8 per cent.; the third gave 20.3 per cent.; the second gave 10 per cent.; the first gave 2.7 per cent.

The estimated percentages, with the mask, were as follows: The longest tube, No. 4, gave 1 per cent.; the next, No. 3, gave 1 per cent.; the second, No. 2, gave ½ per cent.; the first, No. 1, gave 1-10 per cent.

It might be well to emphasize here the difference between the stertor of any closed method and the stertor of the vapor or drop method. The stertor of the closed, or to-and-fro breathing method, is caused by carbon dioxide, which is, comparatively, very safe. In the vapor method, it is caused by the toxic effect of the drug administered, and this is positively dangerous, and should never be permitted to occur.

With this inhaler, then, it is possible, first, to give either a pure chloroform or ether vapor, or any combination of these two drugs, varying in intensity as circumstances require, and never giving a drop more than is absolutely necessary. In an emergency, oxygen can be given without disturbing the inhaler or the mask. Weak, anemic men, and the majority of women, can be anesthetized with the ether vapor alone. Second: Whenever a change is indicated from the one narcotic to the other, it can be done easily and smoothly by simply turning a lever. It is conceded that deaths have occurred by persistence in one or the other anesthetic. For instance, if, in giving chloroform, circulatory depression or other signs of shock assert themselves, ether should be substituted at once. If, in using ether, the secretions from the buccal and respiratory membranes become so excessive that a free air way is maintained with difficulty, it is contraindicated and chloroform should be substituted, as soon as the mucus is removed. The method is not suitable for a pure ether narcosis from the start, except with children, or with the very old or infirm. Nor is it desirable, as chloroform is easier to inhale and quicker in operation, and there is no danger with the attenuated chloroform vapor.

The advantages of this form of anesthesia over all others are:

1. The induction stage is very pleasant (comparatively) for the patient. For a woman, I usually place in the third bottle her favorite cologne; for a man, a "highball," or something similar. The moral effect of the cologne on the one, and the immoral effect of the "highball" on the other, both have their usual quieting tendency, and the element of fear is reduced to a minimum. The anesthetic is started with a one-per-cent vapor of this cologne or whiskey, and, as soon as the mucous membranes have become accustomed to this, a fractional per cent. vapor of chloroform is added for the first minute, and this is changed gradually, but as rapidly as possible, so that at the end of three minutes the patient is getting one per cent. vapor of chloroform and a fractional per cent. of cologne or highball, after which the latter is turned off entirely. The average time to induce surgical anesthesia is six minutes, varying with the patient. After surgical narcosis is established, the third bottle is taken out, emptied, and refilled with hot water at about 100° F. When the chloroform or ether vapor is passed through this hot water, it is raised to the temperature of the blood, making it safer as regards life, and also more respirable, and still further reducing the after-effects. Or the cologne can be sprinkled on the mask, and hot water used from the first in the third bottle. A very satisfactory method is to use the gas ether sequence as a preliminary, and then allow the reflexes to become active, when the oxygen-chloroform vapor should be begun. Another method—as already advocated in a previous paper—is to commence with gas, then change to the vapor mask upon which 10 c.c. of ethyl chloride has been poured, and continue with the chloroform vapor and air. After the operation has commenced, allow oxygen instead of air to flow through the chloroform. Still another method is to dispense with the gas and commence with the vapor mask, using ethyl chloride at the start. A solution of cocaine may also be used, by means of the third bottle, for the first minute or so. If I am to judge from the various suggestions offered by the different surgeons to whom I have mentioned the subject, this third bottle is a veritable Pandora's box.

2. A second advantage of the vapor method of anesthesia is the fact that excitement is usually absent, or so very slight that it is unobjectionable, even in private practice.

3. In the surgical stage the patient's breathing is regular and natural. The lid reflex is never entirely abolished, nor do we have the stertor or snore, or

the mucous râle, even when giving pure ether. We have complete relaxation without the slow pulse of chloroform (as usually administered), or the billowy breathing and rapid, bounding pulse of ether. The breathing and pulse are usually normal throughout the administration, except for fluctuations that may accompany the surgical procedure. In fact, the breathing is so natural that in the majority of cases it is unnecessary to hold the jaw forward. This method will appeal at once to those who prefer, or who have been in the habit of using, the drop method, as the principle is the same, the dosage more accurate, and the narcosis more even. It is also safer, even in the hands of the occasional or inexperienced anesthetist.

4. The small amount of the anesthetic used. As with my mask it is impossible to determine accurately the exact amount consumed by the patient, no figures will be given as rough estimates; but the total amount used, in spite of much waste, is remarkably small, and has been commented upon by many surgeons.

5. In the majority of cases, absence of unpleasant after-effects; this includes scalding the face with the anesthetic, which is an impossibility with this method.

6. The technique can be acquired much more rapidly than any other anesthetizing method.

7. As we know, approximately, what percentage a patient is getting, a continual narcosis is maintained without any danger whatever to the patient. An intermitting narcosis, which is wrong in principle, is thus always avoided.

Oxygen should be used whenever possible, especially with chloroform, as it has now been proven beyond a doubt that this combination is safer than ether and air. Neudorfer, of Vienna, is credited with being the first to use this combination, about 1886; but a careful search on my part has failed to discover anything he may have written. In 1895 it was used by Dr. Schall, of Brooklyn, and Dr. Northrup, of Philadelphia. In one hospital in Pittsburg it has been the routine anesthetic for more than nine years. The exact relation of chloroform and oxygen to other anesthetics was not absolutely established until my own experiments in 1904. It maintains a normal respiration and circulation; increases the limits of safety more than two and one-half times, as compared with chloroform and air; eliminates the mucous râle; and reduces the after-effects to a minimum. Sudden cessation of the vital processes, such as sometimes occurs with chloroform administered in the usual way, never takes place with oxygen and chloroform. In my experiments in the laboratory upon lower animals, the blood pressure always falls gradually, even with a saturated vapor. I may add that in more than one hundred experiments, with either air or oxygen as the combining element, in not a single instance did the heart and respiration stop simultaneously, but the respiration always ceased first. With oxygen, the heart always continued to beat longer than with air. With oxygen also, I was invariably successful in maintaining life after respiration had ceased, provided that artificial respiration was commenced before the heart ceased beating. I have sometimes failed, under similar circumstances, when air was the combining agent.

Dr. Roth, and other chemists, have found, after repeated tests, that there is practically no difference between unused chloroform and that with which oxygen has been combined. These tests included the boiling point, specific gravity, reaction to litmus paper and to silver nitrate, and the action on sulphuric acid, etc. There is, therefore, no objection to using the chloroform a second time.

With my apparatus, as compared with Dr. Braun's, I always use chloroform and oxygen whenever, and as long, as possible, and continue the anesthetic with ether whenever this latter is indicated. The usual precaution of not giving ether in the presence of an open flame applies with double force to the more explosive mixture.

Oxygen and chloroform is especially indicated in all nose and throat operations where a mask would be in the way, and the anesthetic is given through a tube. This tube should never be thrust directly within the trachea—if the operation necessitated some such procedure—but should be held one-half to one inch above, to insure a plentiful admixture of air. With the Junker bottle it was sometimes almost impossible to maintain the proper level of anesthesia in operations such as excision of the tongue. With the larger-size bottle that I use, and the varying percentages available, the narcosis is easily and satisfactorily maintained. When much blood unavoidably gets into the throat I invariably switch to the stimulating anesthetic, ether.

Oxygen and chloroform is also indicated in all operations where vascular turgescence or billowy breathing is undesirable. In addition to the tube,

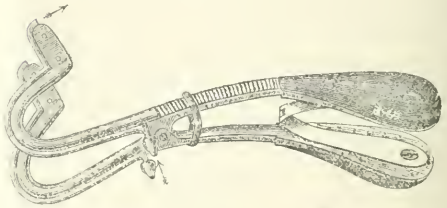

Fig. 6.—Hewitt's modification of Mason's gag, for use in operations within the mouth and nose.

Hewitt has introduced a gag (Fig. 6) consisting of bent metal tubes brazed to the arms of an ordinary Mason gag. He has also introduced a chloroform prop (Fig. 7), through which the vapor

Fig. 7.—Hewitt's chloroform prop.

is passed. Hewitt states: "I find a silk catheter of great use for passing through the nostril to the back of the pharynx." Three years later Dr. Crile, of Cleveland, Ohio, published an account of this method, enlarging on the technique as follows: "Cocainizing the pharynx, the mouth well opened and the tongue drawn out, the entire pharynx then is packed with gauze, the pressure against the base of the tongue being sufficient to control most of the hemorrhage. The patient may thus be placed in any position, regardless of the blood." This has since become known as "Crile's method."

A mouth gag and a metal tube are amply sufficient, in my opinion, for all operations in this region. "Crile's method" presents so many practical disadvantages that it hardly pays for the valuable time wasted in packing the pharynx. The principal objection is that it is impossible to absolutely prevent

leakage, and it is therefore impossible to know how much blood may be in the patient's throat. Nor can you remove the blood without removing the packing. I prefer to see what is going on in the patient's throat, and to remove all blood by rapid sponging.

The change from air to oxygen should not be made usually until the patient is well under the anesthetic and the operation has begun. This is my rule for two reasons; first, the time taken to reach surgical narcosis is much shorter with air than with oxygen; second, from what has already been said, it is understood that this is a very light and even anesthetic. If there is any delay in commencing the operation after surgical narcosis is reached, and the patient gets into a state of false anesthesia, the reflexes are more easily remedied with the hand bulb than with the stream of oxygen. On the other hand, after the operation has commenced, it is easier to maintain the desired level of anesthesia with the oxygen. The anesthetist has also the use of both hands, and can give his undivided attention to the patient.

Let us now compare this method with others:

1. The drop method. There is very little danger in intelligently administering chloroform by the drop method, provided the bottle is placed in water hot enough to raise it to the temperature of the blood (100° F.). Replacing the bottle from time to time will keep the temperature at the desired level. The objection to this method, as ordinarily used, is that it depends on the patient's breathing, whether deep or shallow, as to the vapor percentage inhaled. Inhaling a large amount of cold chloroform vapor in this way sometimes has a cumulative effect that is fatal. This danger is eliminated with the "vapor method," as the patient inhales only the percentage administered, and no more. The adverse criticism of anesthetic mixtures, as usually administered by the drop method, that, after a given time, when you desire a light anesthetic, you are giving a heavy one (the lighter constituents of the mixture having evaporated), does not apply when such mixtures are administered by the vapor method. The anesthetic can be lightened at any time by changing the tube through which the oxygen or air may be passing.

2. The gas-ether sequence. This is undoubtedly the quickest and safest routine method of anesthetizing, and certainly, by comparison with others, very satisfactory; but it is unphysiological—as is any closed method—and for this reason will probably be superseded by the "vapor," or some other, method in the near future. The longer the anesthesia, the less oxygen the blood is capable of absorbing, and the less carbon dioxide it is able to throw off. This condition is intensified by any closed method; but it is corrected by the vapor method with oxygen, and at the same time the plane of anesthesia is satisfactorily maintained.

With this apparatus, then, the vapor percentage can be increased or decreased, with the same flow of oxygen, or air, according to the tube through which the oxygen or air is allowed to flow. This result can also be accomplished by increasing or decreasing the flow of oxygen or air through the *same* tube, or by combining the two methods.

# THE ETIOLOGY AND ELIMINATION OF DIABETES.

By G. LENOX CURTIS, M.D.,

NEW YORK.

MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION, AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE, NEW YORK STATE MEDICAL ASSOCIATION, MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK, HARLEM MEDICAL ASSOCIATION.

Of the entire list of recognized diseases to-day, there is undoubtedly none whose pathogenesis is so little understood as the one which forms the subject of this paper; and for this reason its treatment up to the present time has been very unsuccessful and unsatisfactory.

It has long been known that this affection is due to faulty metabolism which, in some way, interrupts or prevents the perfect oxidation of the carbohydrates, more especially the sugars and starches; but to what particular organ or function this faulty action should be attributed is a question whose answer hitherto has never been removed from the field of speculation.

In all the literature bearing upon the subject of diabetes that I have been able to find, there is none in which its etiology is expressed in terms other than those of its symptomatology; hence it is variously classified. By many it is believed to be primarily a disease of the liver, and is treated as such. By others it is considered and treated as if a derangement of the kidneys were the offending cause. Others still, from the fact that lesions of the floor of the fourth ventricle are so frequently accompanied by the appearance of sugar in the urine, are persuaded that it is a nervous affection.

Recently more definite and thorough pathological studies of diabetes have led the majority of investigators to the conclusion that the symptoms which, collectively, constitute this affection, are caused by some derangement of the pancreas, more specifically by some inhibition or vitiation of the secretion from the islands of Langerhans. This view is strengthened by the fact that the digestion of sugar is known to be normally consummated, largely if not wholly, by the secretion of the pancreas.

But just as the pancreatic theory of the origin of diabetes is about to be accepted, we are confronted by the fact that in a series of experiments made by Zambosi upon dogs, the nerves of the pancreas were not only cut, but the ends were tied "in order to compare the behavior of the isolated segments with that of the central portion." In no instance, however, was there any appearance of sugar in the urine. In spite of the result of these experiments, however, there is a preponderating amount of evidence to show that the pancreatic theory of causation has a strong physiological basis of support.

But even if it be true that, in the majority of cases, diabetes originates in an abnormal condition of the secretion of the pancreas, the question what is it that causes this fatal functional defect remains unanswered, and until a correct answer is found no practical progress in the effort to eradicate this serious malady can be made.

As we know the immediate cause of diabetes is

something which interferes with the proper oxidation of certain elements of food, and as we have the most positive evidence that the appearance of sugar in the urine occurs from, or is accompanied with, lesions in organs differing greatly in structure and function, may there not be some common cause which, owing to an inherent or acquired weakness of one or the other of the organs mentioned, is able so to interfere with their normal action that oxidation is inhibited to a degree sufficient to induce the affection we are considering?

I not only believe this view of causation to be correct because it is the only one which fully accounts for and harmonizes with all the known facts associated with the origin of diabetes, but I am confident that I have discovered the common cause—the disturbing element which is responsible for the existence of every case of diabetes irrespective of the nature or location of the lesion to which organically it is most directly related.

*This common and potent cause is syphilis—that Nemesis of evildoers—which ruthlessly invades every organ and tissue of the body, and with its blighting touch vitiates every secretion and deranges every function.*

The importance of this discovery, so simple and yet so far-reaching in its results, is not difficult to comprehend. It demonstrates that certain, well-defined conditions of the system, erroneously believed to constitute an obscure and intractable disease, are, in reality, merely the symptoms of an affection whose origin and nature are thoroughly understood and whose removal is possible by reliable and scientific methods of treatment.

This discovery is not the forced assumption of a theory; it is one of the results of the observations and investigations begun twenty-five years ago and carried on during a period of years for the purpose of discovering the cause of interstitial gingivitis, a suppurative disease of the alveolar process.

In the course of these investigations I found that a great many of those afflicted with gingivitis suffered also from diabetes. Finally I discovered that in all patients affected with interstitial gingivitis of systemic origin, syphilis, either acquired or inherited, could be traced, and that notwithstanding careful and thorough surgical and dental treatment of the affected parts, a permanent cure could not be effected until the patient was subjected to a course of antisyphilitic treatment.

I frequently observed that, in a liberal percentage of such cases, all symptoms of diabetes disappeared under antisyphilitic treatment administered for the eradication of the gingivitis; but so thoroughly was my mind occupied with the endeavor to ascertain the origin of the gingival disease, that for a long time the important bearing of this observation was lost sight of, and it was not until about seven years ago that the nebulous impression that diabetes is one of the sequelæ of syphilis became sufficiently clear to amount to a tangible idea. At that time I told several professional friends of my discovery, but asked them to refrain from giving publicity to my views until I could make them known to the profession in a proper manner.

During the past seven years I have treated twenty cases of diabetes. All of them had either acquired or inherited syphilis. With the exception of two, all were restored to health with every sign of diabetes eliminated. Of these exceptions one was lost sight of and the other was suffering from epithelioma. The average time required to bring about this result was about three months. The sugar usually disappeared from the urine by the end of the second month. In only one of the cases successfully treated has there been any return of the sugar or of any other symptom. In this case, after several days of high living and alcoholism, a mere trace of sugar was discovered. Otherwise this patient, who when first treated was invalided and whose urine contained 9 per cent. of sugar, is now in robust health.

As a result of this clinical experience, I feel that I am justified in declaring that diabetes is a curable affection.

*Diagnosis.*—That every case of diabetes may receive appropriate treatment, the practitioner must be able to make an accurate diagnosis. This could be done from the history of the case alone were the statements of patients always to be depended upon. But because the syphilitic patient is so prone to deny unblushingly the soft impeachment of specific infection, either from the fear that to admit it would be degrading or, as is frequently the case, because he has been told by his physician that the taint has been completely eliminated by a previous course of antisyphilitic treatment, this method of diagnosis possesses only a corroborative value.

Fortunately, there are ways of determining the existence of syphilis independently of any history the patient may give. Syphilis never invades the system unaccompanied by tell-tale signs of its presence.

The most important and reliable of these signs are the eschar of Curtis, which may be seen upon the surface of the gums, cheeks, tonsils, pharynx, and sometimes the cornea and sclera*, and the syphilitic spores which the microscope reveals in freshly-drawn blood. The latter are of special significance because their presence is not only positive evidence that the suspected disease exists, but their disappearance later is indisputable proof that it has been eliminated, and consequently that the treatment may safely be discontinued.

*Treatment.*—The best treatment for diabetes is, from the nature of the case, that which will most readily and thoroughly eliminate the specific poison which has caused it.

The most reliable and satisfactory treatment within my knowledge is that supplied by electro-ozonation. This remedy has been my chief reliance for the past seven years. Its method of application I have fully described in a paper entitled, "The Influence of Electro-Ozonation Upon Disease," which I read before the New York Academy of Medicine in 1901, and which was published in the *New York Medical Journal* of January 18, 1902. This remedy and its action was again described in a paper upon "The Restorative Influence of Electro-Ozonation Upon the Blood," which was read before the section of Medicine of the American Medical Association at New Orleans, and published in the *New York Medical Times.*

For the benefit of those who have not seen these articles, the following brief outline-description of the apparatus by which ozone is generated and forced into, and even through the body, must suffice. The machine consists, practically, of an ozone generator fed by a high tension coil, which multiplies the voltage of the commercial current a million or more times and practically eliminates all amperage. To the generator are attached brushes or corrugated wires, from which ozone is given off in large quantities, and a Geisler or other vacuum tube is connected by a wire cord, through which ozone is forced into and through the body, thereby oxidizing all

* This infallible diagnostic sign of syphilis was discovered by me over fifteen years ago. I fully described it in a paper on "Syphilitic Localosis Alveolaris," which was read before the American Medical Association in 1898.

pathogenic products and reestablishing nutrition and vitality.

Connected with this apparatus is an electric cabinet which generates light and heat, coupled with ozone. Thus the most important elements which enter into the problem of life are supplied in a form to be utilized.

Although, as I have repeatedly demonstrated, treatment by electro-ozonation alone is able to eliminate every vestige of syphilitic taint from the system, still, in order that the patient may receive the benefit of the eliminative effects which some drugs are able to produce, I generally prescribe, in addition to electro-ozonation, such alternatives as mercury and iodide of potassium, and such tonics and sedatives as iron and veratrum viride. The latter is very useful in aiding the passage of the blood through the degenerated tissues, thereby more rapidly removing the syphilitic poison from the system. These remedies are given between the electric treatments in order that patients may have the benefit of everything that is known to be useful in eliminating the disease.

I do not wish to be understood as entertaining the idea that antisyphilitic treatment by drugs alone will not eradicate both syphilis and diabetes, since the latter, I contend, is never a disease, *per se*, but merely an occasional accompanying symptom of the former. Such treatment will, as I know by experience, cure both of these maladies in their initial stages. I am satisfied, however, that in a large percentage of cases the disease is incurable without the aid afforded by some such stimulating circulatory restorer as this ozone-producing current supplies. In many cases of diabetes syphilitic degeneration has proceeded so far that congested areas of variable size exist here and there throughout the body. These are to be found in the brain and spinal cord especially, often taking, as is well known, the form of gummata.

By using the form of the electric current I have described, these congested areas may be located and, by repeated application of the current, dissipated. Evidence that they are being removed is afforded both by the daily diminution of the pain, which the current causes by its passage through them, and by the gradual improvement of the mental dullness and paretic symptoms which the congestion has induced. The fact that diabetes is so prevalent is, to my mind, the best evidence that there exists a lack of means of determining when syphilis has really been eliminated.

A large number of cases of diabetes that have come under my care give a syphilitic history, and say they were treated for syphilis until the attending physician "guessed" that the treatment had been continued long enough. It seems to me there should and must be some definite means of ascertaining, for a certainty, when the system has been freed from *any* disease, and as a result of my experience for a number of years in making microscopic examinations of freshly-drawn blood, after the manner so strongly advocated by Watkins, I feel sure that this method, better than any other, supplies the means of obtaining this desirable knowledge.

The spores of syphilis can be seen in the blood within a very few days after the primary infection; also in the blood of an infant at birth, whose father had contracted the disease before marriage and whose system was still infected with it in spite of the assurance and belief that it had been completely removed by a course of specific treatment. They can even be discerned in the blood of the infected mother months before the child's birth.

How puzzling is the occurrence of diabetes in children! Has ever before a satisfactory explanation of its existence in these subjects been given, or a satisfactory form of treatment pursued? Since the number of spores in infantile cases is relatively small, does it not seem reasonable to suppose that antisyphilitic treatment at this time will be more effective than when applied at a later period?

Syphilitic children bear specific treatment well. It is remarkable how completely a few months of treatment will exterminate all traces of syphilitic infection. To obtain a similar result in adults a much longer time is necessary, because of the greater amount of tissue and blood degeneracy that has occurred. Why, then, not anticipate and prevent the appearance of diabetes by eliminating its cause?

In regard to the restrictions of diet, so irksome to the patient but so universally believed to form an indispensable part of all successful treatment, I am happy to be able to say that under the methods of treatment I pursue I find them entirely unnecessary. Allowing that the sugars and starches are the food elements from which the system derives the greater part of its vital energy, it seems to me that their restriction is more prejudicial to the invalid than to a person in a state of health.

Every sufferer from diabetes, as Dr. Charles W. Banks in a recent article truly says, "must have sugar, or else his own proteids disintegrate and supply it, forming at the same time oxybutyric acid and its derivatives, which poison him." As to starch, the diabetic always has power to digest and assimilate it to some extent, otherwise his tenure of life would be a very short one.

As every one of experience knows, there are diabetic patients who cannot digest certain forms of starches, but who are able to assimilate other kinds with impunity. Von Noorden found that oatmeal agreed with many patients, and the "potato cure" has many advocates. Even "the various commercial gluten preparations," quoting Dr. Banks again, "which are usually introduced into the diet upon the exclusion of the carbohydrates, contain, according to Sherman and Burr (*New York Medical Journal*, October 12, 1901), a starch content fully as large as is found in ordinary wheat flour." Dr. Hughes of England sounded the keynote of the true therapeutics of diabetes when he said, "until we can do more than cut off supplies; until we can attack" (and let me add, conquer) "the morbid process itself, we cannot consider ourselves in a condition to cure diabetes."

In no case do I enjoin my patients from using the carbohydrates freely, and it is to this fact that I attribute their comparatively rapid recovery, for so great is the restorative power of electro-ozonation over the processes of digestion, assimilation, and elimination, that the system derives all the nutritive benefits which these highly important foods are able to supply.

In conclusion I most earnestly urge physicians to test this method of treating diabetes. If electro-ozonation is not available, use the ordinary antisyphilitic treatment; but if the two can be used conjointly, the desired results will be not only more satisfactorily, but also more speedily, attained.

7 West Fifty-eighth Street.

**A Method of Extracting the Fetal Head When Torn From the Trunk.**—Bensinger describes a plan he employed with success in two cases. In each case a strong-toothed clamp was fixed to the base of the skull, and to the protruding handle a cord was tied. A weight of about three pounds was attached to the other end of the cord, and was allowed to hang down over the foot of the bed. The gradual traction caused the spasmodically contracted cervix to relax, and about twenty-four hours later the head could easily be pulled out by means of the clamp. —*Zentralblatt für Gynäkologie.*

# THE COST OF MODERN HOSPITALS.*

By S. S. GOLDWATER, M.D.,
NEW YORK.
SUPERINTENDENT OF THE MT. SINAI HOSPITAL.

In analyzing the costs that enter into the construction of a modern hospital, and in attempting to state the extent to which the customary expenditures of the period are justified, I shall not go back very far, because a comparison of present methods of construction with those of a hundred years ago would not be especially useful to this audience.

I assume that the purpose of the present discussion is to make somewhat clearer the reasons for planning and building a hospital like, let us say, the present Mount Sinai Hospital in New York, or the more recently completed Akron City Hospital in Ohio, and not like the older wings of the Massachusetts General Hospital, or like any typical hospital of a generation ago. At that period the use of fireproof materials in hospital construction was not deemed indispensable; principles of asepsis were unknown; organized nursing was in its infancy; the hospital household was an overgrown and disjointed family group and not a highly systematized, scientific, and business organization.

Hospital construction in the past generation has shared in the economic oscillations and in the esthetic development of the time. In most American cities building construction for any given purpose is more costly now than it was five years ago. Competent authorities say that brick buildings with wooden joists, board floors and lath and plaster walls, were built in 1870 for 25 per cent. less than the prices prevailing to-day; that is to say, materials and labor are dearer in themselves, quite apart from any change or improvement in actual construction. This is an economic accident which has nothing to do with hospital construction as such, but it must be given due consideration in the treatment of the question before us.

The influence of art is also entitled to a moment's consideration, for esthetic progress has not been lacking in expression in the construction of modern hospitals. In the original design of the new Bellevue Hospital, the erection of which in New York City is about to be begun, a striking dome capped the central structure. This feature has since been discarded as a superfluous ornament bearing no organic relation to the hospital itself; but it will serve to illustrate a distinct tendency toward the use of nobler materials and more ornate designs, at least for the principal fronts of important buildings—a tendency to which hospital architects have yielded in their turn. To what extent hospitals may justly be made to minister to esthetic demands, is a question for the consideration of social philosophers, and mere allusion to it here will suffice. Whatever the answer may be, it need not greatly concern us, because this element of cost has not increased in the past generation sufficiently to affect seriously the financial problems of hospitals.

*Actual Costs Compared.*—What, then, is the increased cost of hospital construction which is to be analyzed? The hospital of 1870—I mean the average town hospital—was built at a cost of about 15 cents per cubic foot. The exterior was simple; the plumbing and heating were of a kind now regarded as rudimentary; the building was not fireproof and was finished with wood and plaster on lath. Such a hospital could be duplicated in New York to-day, if the building laws allowed, at a cost of 20 cents per cubic foot. Allowing for all purposes 6,000 cubic feet per patient (an unusually liberal allowance for 1870) the cost of a hospital of 450 beds, or 2,700,000 cubic feet, would be $540,000 or $1,200 per bed. Now compare with this the most recently constructed general hospital in New York City, a hospital built to accommodate 450 patients. This building, or group of buildings at the prevailing market rates for construction, would cost 40 cents per cubic foot. (The actual cost was nearer 35 cents per foot, but the contract was made at a moment favorable for the hospital and could hardly be duplicated to-day). If the old space allowance prevailed, namely, 6,000 cubic feet per patient, a modern hospital of 450 beds would cost just double the price of a brick and wood hospital of the kind I have described; that is, $2,400 per bed, instead of $1,200.

But the new hospital just mentioned has a total contents of some 5,000,000 cubic feet, or 11,000 cubic feet per patient; and the cost of such a hospital built to-day in New York City upon the plan of the hospital to which I allude, would be $2,000,000 or approximately $4,400 per bed. This figure is high because the average or per capita space allowance is unusually large. The smaller Akron City Hospital, built for a similar mixed service of public and private patients, can accommodate only 60 patients and is said to have cost $203,000 or $3,300 per bed. The Fordham Hospital now being built under the auspices of the Board of Trustees of the Bellevue and Allied Hospitals of New York, will cost $600,000 and will accommodate 150 free patients, making an average cost of $4,000 per bed. The new Bellevue Hospital, planned for 2,400 free patients, and estimated to cost 40 cents per foot, will allow 9,000 cubic feet per patient and will cost not less than $3,600 per bed. The significance of the Bellevue figures is accentuated by the fact that while living accommodations for a limited number of male nurses are included in the plans, quarters for the much larger number of female nurses are not called for. These nurses are to be cared for in a neighboring but independent establishment, the cost of which should, in comparative tables, be added to the figures given.

*Cost of Foreign Hospitals.*—It may add to the interest of the argument, but it will not help us much, to compare with these figures the costs of certain typical foreign hospitals—some of them not so recently built, but all ranking as modern. In Germany under quite different economic conditions and with a simpler type of construction, costs have been relatively low. The Hamburg-Eppendorf Krankenhaus, built nearly twenty years ago for 1,500 patients, cost 3,480 marks or $870 per bed; the municipal hospital in Berlin known as the Urban Krankenhaus, which accommodates 600 patients, cost $1,075 per bed; and "Friedrichshain", under the same management, cost $1,500 per bed. To turn to France, it may be noticed that the Lariboisiere, a monumental pavilion hospital built in Paris about fifty years ago and accommodating about 600 patients, cost $3,250 per bed. St. Thomas' Hospital in London has accommodations for 558 patients and its cost of construction was about the same. The costliest hospital in London is the Belgrave Hospital for Children, built for 78 patients at a cost of $3,500 per bed. The Royal Victoria at Belfast, on the other hand, presents an example of a recently

*Read at the seventh annual meeting of the Association of Hospital Superintendents, Boston, Mass., September 27, 1905.

constructed hospital embracing seventeen large wards and costing only $1,500 per bed.

**Analysis of Increased Cost.**—In the first rough analysis there appear to be two main elements of increased cost—first, better or different materials, and second, a greater space allowance per patient. The prevailing high cost per unit of space is not due merely to the substitution of relatively costly for relatively cheaper materials, but is due as well to the fact that the variety of materials and the cost of incidental workmanship have been increased in virtue of the introduction of new methods of building, heating, ventilating, and lighting, and, above all, on account of the application of new principles of hospital management. It will appear from what follows to what use the new materials have been put and to what purposes the additional space is devoted.

*Protection against Fire.*—A great leap upward in cost was taken with the substitution of fireproof for inflammable building materials. This change was due in some instances to an awakening sense of responsibility for the lives of hospital inmates, while in others it was compelled by law. Similar ends have been served by the introduction of independent fire pumps in connection with interior stand-pipes. The necessity for the protection afforded by increased expenditure in this direction is so obvious that I shall not attempt to justify it by argument.

*Heating and Ventilating.*—More debatable ground is approached, however, with the introductiou of the subject of heating and ventilating. The cost of a modern boiler, heating, and ventilating plant, in a hospital of liberal dimensions, is about 5 cents per cubic foot. This figure includes automatic heat-regulation, and a double system of air ducts and air fans, one for supplying fresh air, the other for withdrawing vitiated air—features which thirty years ago would have been omitted. The boiler plant and heating system then in vogue cost about 2.6 cents per cubic foot, or about one-half the prevailing cost. Granting a space allowance, for all purposes, of 9,000 cubic feet per patient, it appears that the increased cost of modern methods of heating and ventilating is $215 per bed.

The testimony of modern engineering authorities is all in favor of the expenditure of this sum for the purpose under consideration; and any book on hospital hygiene nowadays would seem incomplete if it did not embody the recommendation of an artificial system for changing the air of hospital wards. Yet experienced hospital managers concede that hospital wards really have been and can be pretty well ventilated without the use of propulsion and suction fans; and curiously enough, I have found fans to be of greatest use, not in rooms occupied by patients, which with proper exposure to natural atmospheric currents and with a judicious use of windows and transoms may be made to take care of themselves, but in operating rooms having no natural means of ventilation, and in kitchens and laundries and laboratories where disagreeable odors, steam, and the gases of chemical decomposition, rather than bacterially-contaminated or breath-contaminated air, threaten the health and comfort of the occupants.

It would be interesting to continue the very practical investigation begun by Dr. Holmes of Cincinnati, who recently discovered many instances of the complete or partial neglect of costly apparatus originally intended for the ventilation of hospital wards. So much has been written upon the subject of hospital ventilation that one is strongly tempted to assume that the last word has been said, and to adopt without question the recommendation of the latest writer. Dr Holmes' disclosures, however, show the danger of such a course, and suggest the wisdom of a reconsideration by hospital managers of the entire subject of artificial ventilation, with a view to the discovery of an irreducible minimum of apparatus for this purpose.

*Electric Light and Power.*—We have seen that boiler-cost has increased in part on account of the introduction of ventilating fans. Another part of the increased cost of hospital boilers is due to the introduction of electric lighting and power plants. The electric light nowadays is regarded as indispensable; and electric power is used to advantage in hospital laundries and machine shops, and for the operation of elevators.

The superiority of electric light over gas illumination, from the standpoint of atmospheric contamination, is indisputable; but aside from this it is important to remember that the electric light lends itself to clinical uses in the shape of portable lamps for the inspection and exploration of the body, to which gas never was adapted. Moreover, after the installation of the plant, the cost of electric lighting, estimated on the basis of the candle power or unit of illumination is not high as compared with that of gas.

Let me say a word of caution in regard to the distribution of electric lights in hospitals. Architects who do not consult the judgment of those who are familiar with hospital needs are disposed to scatter electric fixtures through the hospital with a profusion more generous than wise. Wards do not need to be brilliantly lighted; strong light is occasionally needed at the bedside at night, but portable lights attached to suitably located receptacles may be made to furnish such light precisely where and when it is needed, and nowhere else.

Taking into consideration the needs of the whole hospital, I believe that an average allowance of one 16-candle-power lamp to 800 cubic feet of interior space will suffice. The distribution, of course, will not be uniform but will vary with local needs.

*Water Supply.*—The subject of water supply will detain us but a moment, because the attempt to insure the safety of the water supply of hospitals has added only slightly to the cost of construction. The cost of a filtering plant for a hospital of 500 patients may be estimated to be $7,500 or $15 per bed. Few American cities are at present in a position to insure the safety of the water delivered by them through the public mains; and hospitals are therefore often justified in installing filtration plants which not only protect their inmates, but which incidentally diminish the wear and tear on pipes and fixtures resulting from the physical impurities which are to be found in the ordinary unfiltered supply.

*Laundry.*—If we turn now to the housekeeping departments, we shall find that the requirements of these departments have grown, but in a modest way. Laundries are expected to turn out more work than they were called upon to do twenty or thirty years ago. Trained nurses are more fastidious than were the attendants who preceded them, and asepsis places no limit upon its demand for sterile towels and bedclothes. Hence laundries need more space than formerly. They require also an equipment of heavy and costly machines; but laundry machinery represents an

outlay ultimately profitable because such machinery is distinctly labor-saving.

*Refrigeration.*—It is not in the laundry alone, among the housekeeping departments, that we find an increased use of machinery and apparatus which brings these departments into close touch with the engine and boiler room. A similar dependence is noticed in refrigerating rooms, which, in the modern hospital, are commonly cooled by the circulation of either brine or ammonia From the standpoint of convenience, the new method of refrigeration is superior to the old, and its general introduction in large apartment houses, as well as in institutions, indicates that the cost of operating such a system is not materially greater than the cost of maintaining an ice supply.

*Kitchen.*—Marked improvement has taken place in the construction and equipment of kitchens. Kitchens indifferently lighted, poorly ventilated, and finished principally in wood, were once acceptable to hospital managers. The standards of the present time are less economical. The kitchen of the modern hospital has a floor of tile, terrazza, or cement, and walls of glazed brick; it is spacious, is located frequently in a separate building and its artificial system of ventilation is carefully planned. The modern kitchen is supplemented by refrigerator rooms, storerooms for dry and wet groceries, and often by a bake shop, a receiving room and an office for the person in charge.

These features are due to a desire to make the whole hospital clean and businesslike, and to the wish to recognize the rights of hospital servants as well as of patients. In a large percentage of cases the illnesses of patients occupying beds in hospital wards can be traced to exposure to unsanitary conditions in factories and workshops. The hospital worker is entitled to protection from such influences, whatever the cost.

The cost of kitchen equipment, as distinguished from the construction of the bare rooms occupied for kitchen purposes, has increased during the past thirty years about 33 1-3 per cent. Labor-saving devices have tended to decrease the cost of production of the fixtures used, but many fixtures have been added. Formerly the list included a range and broiler, a carving table, steam-jacketed kettles, coffee and tea urns, a bake-oven, and possibly a single plate-warmer. To-day plate-warmers are found not alone in the kitchen, but scattered through the hospital; dish-washing machines and steamers have been introduced in the kitchen proper, and the dietician demands steam roasters, cereal kettles, potato mashers, meat cutters and ice cream freezers, with their accompanying steam-fittings and electric motors.

The purpose of the additions enumerated is either to save labor or to improve the service of the department; and this purpose is successfully fulfilled.

*The Ward Unit.*—We can boast of very little theoretical knowledge upon the subject of hospital wards beyond that which was contributed in 1788 in the report of the Commission of the French Academy of Sciences which had under consideration the construction of a new municipal hospital for Paris. Unfortunately the recommendations of that commission were not speedily put into general practice; and to-day there are public hospitals in Paris which are more rudimentary in their construction than the hospital planned by the commission of 1788.

The most notable change in the actual construction and arrangement of the ward unit, in modern American hospitals, is the utilization of a constantly growing number of material-consuming and space-demanding ward accessories. So far as general hospitals are concerned, the cubic contents of the sickroom proper, that is, its per capita allowance, has not notably increased. In isolation wards the interval between beds wisely has been extended, and in the modern isolation hospitals of the Metropolitan Asylums Board of London, 2,500 cubic feet per bed within the ward proper, is not regarded as excessive.

In general hospitals the ward unit now includes a day room and dining room for convalescents, a special closet for a portable tub, not less than two quiet rooms for each ward of say twenty-four beds a dressing and examining room, a small laboratory for the rapid examination of clinical specimens, bath room and toilet, a commodious pantry, a closet for the drying of blankets and a linen and supply room. All of these features demand space, and every addition to the list of accessories implies an incidental increase in the cost of passages or corridors for communication.

Again, some of these rooms are fitted up in an expensive manner. Hard-wood floors are used for wards and quiet rooms. The bath room, pantry, toilet, examining room and laboratory are finished in even more expensive manner; tile or terrazza floors, tile walls, marble partitions and shelves, and copper and slate or glass or soapstone fixtures are introduced wherever the use of these materials tends to satisfy the claims of hygiene.

While high-class construction is now the rule, I have seldom seen anything like wilful extravagance in ward construction. Here and there an architect or a building committee may allow too much space for bath rooms, or may install a larger number of bath tubs than the hospital service requires; occasionally water closets are supplied with too free a hand; and rarely a convalescents' day room is a few feet larger than is actually required, but reasonable standards are gradually being established through the study and avoidance of the mistakes of earlier builders.

*The Surgical Department.*—The proportion of surgical cases in hospitals is greater to-day than it was a generation ago, and the demand for surgical beds continues to grow. Operating facilities, therefore, have been and need to be increased. Operating rooms are more numerous and their construction and interior finish are better, safer, and more costly. Extravagance is occasionally encountered, as in the erection of operating amphitheaters in hospitals in small towns where there are no large groups of students; but in the main the development of the operating department represents an approximation towards asepsis and hence towards greater safety for the patient.

In a busy hospital, at least one operating room should be held constantly in reserve, in order that an infected room may be put temporarily out of commission, for thorough cleaning and disinfection. The additional room costs money but saves life. For the ordinary work of the hospital, there must be separate rooms for clean cases and pus cases—a distinction which should always be rigidly maintained.

*Disinfection and Sterilization.*—The modern hospital is not complete without its sterilizing apparatus. From the boiler plant a supply of steam is derived for the central disinfecting plant which protects the hospital from epidemics; for the apparatus for sterilizing surgical dressings; for the water sterilizing cylinders; for the instru-

ment sterilizers in operating rooms, wards, dispensary and autopsy rooms, and for the thermostats, vats, autoclaves, and water-baths of the drug manufacturing room and of the pathological laboratory. The use of all this apparatus implies a highly differentiated working force, and throws light on the necessity for accommodating a relatively large staff of attendants. It suggests the expansion of all of the departments associated directly with the treatment of patients, with the handling of infected materials derived from patients, and with bacteriological and pathological research. Let us consider, briefly, the present needs of the groups of workers who form the personnel of these departments.

*The House Staff.*—The house staff of the modern hospital is a formidable body, whose presence demands liberal space allowance for sleeping rooms, dining rooms, lounging room and library. Thirty years ago a staff of four physicians might have been found in a hospital of 200 beds. To-day more than three times that number are required to do the necessary work; and alongside of the medical and surgical house officers, there has grown up a new division composed of workers in bacteriology, pathology, and chemistry. For the scientific work of these men, who contribute so much to the success of the modern hospital, the more prosperous institutions provide separate buildings, built and equipped at a high cost per unit of space. Even the least pretentious hospital has its pathologist, and provides for his work as generously as its means allow.

*The Nursing Force.*—The nursing force of to-day must be reckoned with liberally. The relative number of nurses in the wards has increased, and a large part of the work of the nursing staff is done in the nurses' home. The home has grown; the quarters of the individual nurse have been improved by the substitution of costly single or double rooms for large and cheap dormitories; class rooms and demonstration rooms have been added to the accommodations of the department. The increased outlay involved in these arrangements will not be criticised by anybody who appreciates the dependence of the hospital upon the endurance, the training and the devotion of its nursing staff.

*Accommodations for Minor Employees.*— The minor employees of the older hospitals were not well treated. Many of them worked in the hospital for trifling wages during the day and were compelled to find lodgings for themselves outside of the hospital at night. For others, lodgings within the hospital were provided; but these lodgings were rarely planned with proper regard for their occupants. They consisted, perhaps, of discarded outbuildings or basement rooms, pressed into wretched service as dormitories for a class of employees who, by their labors, contributed as truly to the support of the hospital as did the voluntary subscribers to its maintenance funds. The hospital which provides decent surroundings for its staff cannot be criticised for the expenditure of the sum necessary for this purpose.

*Special Departments.*—I have already referred to the increased subdivision of labor in hospital work. Among the special departments are the *x*-ray department, with its costly outfit; the hydrotherapeutic department with its cabinets, douche-tables, steam supply and refrigerating arrangements; the ward for consumptives—all tending to swell the construction account and to increase the amount of space allowed to the individual patient.

Suites of rooms are now provided in some hospitals for private patients, but the provision of such accommodations is regarded as an expense only by the superficial observer. The expenditure of money for this purpose, if suited to the size and social status of the community, adds to the net income of the hospital.

*Outdoor Department.*— In analyzing the cost of hospital construction, due allowance must be made for the cost of the out-patients' building. It would be quite logical to exclude this department from estimates of the cost of the hospital plant, but I have done otherwise in the quotations given in deference to the common practice, which is to include in the general figures this very considerable element of cost. Dispensaries are nowadays planned commodiously, are subdivided into a large number of special departments, and tend to occupy a constantly growing proportion of the buildings to which we habitually refer as "the hospital."

*Observation and Isolation Wards.*—An important feature of the modern general hospital is the observation or reception ward, where new patients are received and prepared for a clean and safe entry into the general wards. From three to five per cent. of the whole space of the hospital may be devoted advantageously to this purpose; yet the beds in these wards which enhance so materially the cleanliness of the general wards and which serve as a protection against the introduction of contagious cases do not augment appreciably the normal capacity of the hospital as a whole.

Every hospital, even those not intended for the reception of contagious cases, must have facilities for isolating dangerous cases which unexpectedly develop in its wards. An isolated pavilion, suitably subdivided for the simultaneous reception of several contagious diseases, is a necessary part of the complete hospital. Its wards and rooms may be unoccupied most of the time; but the day inevitably comes when the need of the pavilion is felt and when the wisdom of its construction is recognized.

*Branch Hospitals for Convalescents.*—After this brief inquiry into the causes of increased cost of construction of modern hospitals, what shall be our answer to the question how far this increased cost is justified?

Aside from economic causes which are beyond our reach, the high prevailing cost of construction is apparently due to new methods of disease-classification and treatment, to more intense nursing, to the discovery of scientific methods of diagnosis, to an application to the principles of hygiene to wards, work-rooms and living rooms, to the desire to release from the wards during part of the day convalescents to whom the atmosphere of the sick room is detrimental, and finally, to the evolution of the fireproof, and to a certain degree germ-proof, building. If we apply to all of these improvements the rigid test of results, we shall find that the test is fairly met; but while we may grant that to build a general hospital embodying all of the features enumerated is to tread the path of wisdom, we may nevertheless question the propriety of investing all of our capital in the construction of such a plant.

In my opinion, no general hospital is complete, no acute hospital service is all that it should be, unless it is associated with an establishment for the more economical treatment and more rapid cure of convalescents. The idea of the branch hospital is not new, but the economic principle which underlies it, so far as I am aware, has never been stated with sufficient emphasis by hospital writers. The failure of hospital managers to

grasp this underlying principle of the division of capital and labor is almost incomprehensible. In industrial and commercial enterprises, the principle is applied as a matter of course. Manufacturers who rent at fabulous prices showrooms on Broadway or Regent street, would not dream of occupying such expensive premises for the work of their factories, because they know that factories can be built and operated to better advantage in the suburbs; but in the management of hospitals a similar distinction has not been made.

It may be said that convalescent wards and homes already exist: but the field is not covered by such convalescent homes as have been already established, and it never can be covered by convalescent homes which systematically refuse to receive all patients suffering from open wounds, or in fact, any patient requiring even a slight degree of medical care. The branch hospital here advocated must have a medical and surgical staff (though a small one) and it must be prepared to receive, and if necessary to continue the treatment of patients whose convalescence can be hastened by a change of air and scene, but whose treatment no longer demands the expensive and complex resources and conveniences of a great modern hospital.

Burdett reports that the London hospitals have recently acquired the right to send to the Swanley Hospital Convalescent Home a certain number of patients suffering from open wounds but no longer requiring the care of a highly skilled surgeon nor the facilities of elaborate operating rooms. It is customary, Burdett writes, to remove these patients to the country as soon as the surgeon finds that the cases have reached a stage at which this course can be safely followed. The average residence in London hospitals of the class of cases which it is now customary to transfer, was formerly thirty-five days. Country surroundings have reduced the average length of treatment to nineteen days. From this point of view alone the gain is considerable, but the economic meaning of the branch hospital is more far-reaching and more striking than these figures indicate.

*Comparison of Costs With and Without Branch Hospitals.*—Suppose a committee to have $1,000,000 to invest in a general hospital. If the most approved methods of hospital construction are followed, this sum will build, let us say, 2,500,000 cubic feet at the rate of 40 cents per foot. Let us assume that 10,000 cubic feet is the average space per patient required for all purposes (not an extravagant estimate if due allowance be made for nurses' home, private pavilion, dispensary, laboratories, and housekeeping and administrative departments); on a basis of 10,000 cubic feet per patient, the capital sum of $1,000,000 will build a hospital of 250 beds at an expense of $4,000 per bed. Let us suppose that such a hospital has been built and that all of its beds are occupied. At any given time there will be found within its walls, say fifty patients no longer acutely ill—patients who, with advantage to themselves, might be moved to a country home of simple construction and inexpensive organization. In order to provide in a rational way for this group of patients (a group always to be found in large general hospitals), funds for hospital construction should be divided at the outset into two parts: one part, the greater, should be devoted to the erection of the main hospital in the city, the other part, the lesser to the construction of the branch hospital in a neighboring suburb.

Now, what will be the gain resulting from this splitting of our capital? If, out of $1,000,000 we spend $800 000 in the construction of a hospital of 200 beds at $4,000 per bed, and the remaining sum, $200,000 in the construction of a country branch of 100 beds at an outlay of $2,000 per bed, the net gain will be 50 beds. In other words, invested as it is now commonly invested, in a single city institution, a building fund of $1,000,000 will provide for 250 patients; invested as it should be invested, in a city hospital with a country branch, it will provide for 300 patients.

Furthermore a city and a country branch aggregating 300 beds, can be operated at an annual cost only slightly exceeding the cost of conducting a city hospital of 250 beds; for while the cost of caring for patients in an acute general hospital of the 10,000-feet per capita type is approximately $2.25 per day, the cost of caring for patients in such convalescent homes as already have been established is approximately $1.25 per day. The removal to the country of the inactive cases adapted to such treatment, and the substitution of an equal number of acute cases in the city branch, will tend to increase slightly the per capita cost of this branch chiefly through its influence on the nursing account; and the cases which it is proposed to transfer to the country will cost slightly more in branch hospitals than is now ordinarily expended for the care of occupants of convalescent homes. But for each unit of outlay the plan proposed will return in round numbers, hospital care for at least 15 per cent. and possibly 20 per cent. more patients than can be reached by the present system. The prevailing system furnishes high-class hospital service for patients who do not need it, and a waste of capital and labor results. This waste can be avoided by the establishment of branch country hospitals.

Time is lacking for a discussion of the administrative relations between the city hospital and the proposed country branch. I realize that a physician or surgeon here and there may object to the dismissal from his ward of a patient who is not entirely cured, but the majority are far too intent upon securing a rapid and acute service, to stand in the way of the plan which is here advocated, and those who are benevolently disposed towards their patients will not oppose a division of capital and labor which on the whole will hasten the favorable results of treatment.

Fifth Avenue and One Hundredth Street.

**Drainage in Acute Diffuse Septic Peritonitis.**—Van Beuren Knott defines diffuse septic peritonitis as an acute septic inflammation of the peritoneum so widespread as to involve the entire surface, accompanied by marked changes in the appearance of the membrane and in the quantity and quality of its fluid contents. This is usually due to perforation of some of the hollow viscera, with extravasation of septic material into the general peritoneal cavity. Perforation of the stomach and duodenum is followed by more rapid infection than perforation of the lower part of the digestive tube. The peritoneum becomes congested, roughened, lusterless, there are beginning adhesions, and the fluid contents are increased. The diaphragmatic peritoneum, especially around the central tendon, absorbs more rapidly than any other portion of the abdominal lining. Hence the sitting position after operation aids in keeping up the drainage of the abdomen established by all surgical operations done for peritonitis. The author has operated on nineteen cases with only two deaths, using this method of drainage. The first step is to find and repair the source of infection. Then make an incision two inches long, in the median line above the symphysis, and insert a rubber drain with an iodoform wick inside it. In females make a counteropening through the posterior cul de-sac into the vagina and insert a rubber drain. Wash out the abdomen with several gallons of hot salt solution, and close the abdomen nearly to the tubes. The fluid is pumped out every two hours through the tube.—*The Medical Herald*

# MEDICAL RECORD.

*A Weekly Journal of Medicine and Surgery.*

## MEDICAL UNION IN NEW YORK STATE.

It is hoped and believed by those who have the interests of the medical profession in this State at heart that the coming week will see an end to the division in our ranks that has existed now nearly a quarter of a century. It is expected that the question of union will be finally passed upon at the meeting of the New York State Medical Association in this city on Tuesday next. The unionists in the Association were defeated last year by a small but active majority who took advantage of a legal technicality to prevent action. According to the law of this State a notice of the meeting at which action looking to the dissolution of the society was to be taken should not only have been sent to, but should actually have been known to have been received by, each and every member of the organization. Unaware of this provision the officers last year merely sent mail notices to the members, and so no vote could be taken. This year the precaution was taken to obtain acknowledgment of service from all the members; those who did not acknowledge the receipt of the notice by mail were served with a personal notice by a court officer who made affidavit that the notice was served. Accordingly there can be no doubt this year regarding the legality of the vote of union, if it is passed.

According to the terms of the agreement which this meeting is expected to put in force, the New York State Medical Association gives up its name and corporate existence and becomes merged into the Medical Society of the State of New York. But in return for this the Society gives up its organization, which is acknowledged to be far from perfect, and adopts that of the Association, which is believed by many to be the best plan of organization ever adopted by a medical body. This plan is practically the same as that since adopted by the American Medical Association and most of the State societies. Those within the Association who oppose union say that the Association, which has had an active and useful existence for twenty-two years, will be wiped out of existence and lose its identity in the larger body. But by the terms of agreement it is only the name that is lost, while the plan of organization —the vital principle of the Association—will be adopted by the united body and live on as the informing soul of the new society. The objectors also say that they will by this act of union, which must be preceded by dissolution of the Association, lose their membership in the American Medical Association, since the Medical Society of the State of New York is not recognized by the national organization. But that objection is met in the articles of agreement, and long before the next meeting of the A. M. A. the members of the amalgamated society will be in good and lawful standing. They seem also to fear that the new society will not adopt the principles of ethics of the American Medical Association, and therefore that they will be excluded from membership in the national body; but even were these principles of ethics not adopted by the members of the amalgamated State Society, the new society would not be outlawed, since the national organization does not demand subscription to these principles as a *sine qua non* of recognition. The question will be submitted by referendum to the vote of the members of the society as soon as practicable after the entry of the order for the consolidation of the corporations, and since it is expressly provided that these principles are merely "suggestive and advisory," it is most probable that they will be adopted. The third objection offered is that the agreement does not provide for the continuation of the Medical Directory, the *Journal*, and the plan for defense against unjust malpractice suits. But these are matters that belong to the working machinery of a society and could not well be incorporated in the formal terms of agreement. If these features are desirable there is little doubt that they will be continued by the State Society; they are much more likely to be adopted if all the members of the Association enter readily into the plan of union and use their influence, as members of the united body to that end.

All these questions, however, have been threshed out in meetings of the Association and its committees appointed to deliberate on the plan of union, and the time for discussion and argument is past. The members of the Association by a very large majority are in favor of union (the proxies of four-fifths of the members are, we understand, already in the hands of those who will vote for amalgamation) and the small minority opposed to unity and concord among the medical men of this State can defeat the project only through the indifference of the friends of the measure. In another column we publish an appeal, which has been sent to all the members of the Association, calling upon them to attend the business meeting on Tuesday next and make effective by their votes the union between the two State societies. We earnestly hope this appeal will reach all the members of the Association and that those who can by any possible means, at whatever sacrifice of time and trouble, attend the meeting will do so. It would be calamitous were the efforts of the peacemakers again defeated, and the scandal of a divided profession continued. The measure, as this appeal says, can be defeated only through the indifference of its friends. We do not believe it will be defeated, but it should be carried by such an overwhelming majority that no question can ever be raised regarding the will and the intention of the Association in voting for union. For the sake of the Association itself, of its dignity and good name, the vote to dissolve the organization should be large and determined; and those who love the Association and have worked for it for so many years, having determined in a large spirit of self-abnegation to sacrifice the name of their body on the altar of a united profession, should do so with pride and not allow the resolution for union to slip through with a bare majority of ayes as though they no longer cared what became of their organization.

## BEHRING'S STRANGE PERFORMANCE.

Professor v. Behring, the putative discoverer and once the patentee of the antitoxin of diphtheria, improved the occasion of the meeting of the Congress on Tuberculosis in Paris last week to make a premature announcement of a new remedy for tuberculosis. A curious thing regarding this was that, although the Tuberculosis Congress was in session at the time, the announcement was made to a reporter of the *Matin*, a daily paper of Paris, and repeated in an interview with a representative of the *Figaro*, and only then was the alleged discovery related to the members of the Congress in a paper read at the last session of that assembly. Another strange thing was the announcement that the remedy will not be available until next August and that even then its composition and mode of preparation will be kept secret. This, however, was in accordance with the principle, of which Behring has always been a conspicuous advocate, that a discoverer is entitled to the pecuniary rewards of his discovery.

It is unpleasant to see a man of Behring's scientific attainments controlled by such a mercenary spirit. But that is of course no argument against the possibility of his remedy being efficacious in both the prevention and cure of tuberculosis. In the paper read on the last day of the Tuberculosis Congress, he said that he had discovered the existence of a curative principle entirely different from antitoxin in its mode of action. It is this principle, he said, which plays the chief rôle in the immunity conferred by his "bovovaccine." The method is based upon the impregnation of the living cells of the organism with a substance derived from the tuberculous virus residing in the yellow tubercle. This substance he has named T. C. The preparation is said to be in the form of a powder. The reports of the paper contained in the press dispatches are not very illuminating, and while it is possible that the scientific reports may be more intelligible, it is not probable that Behring has described his method in any but the most general terms. The fact of the value of some of Behring's previous therapeutic achievements offsets in a measure the inherent improbability of the discovery of a cure for tuberculosis. No one, at least no one entitled to speak with authority, denies at the present day the efficacy of antitoxin in the treatment of diphtheria. One hears less of his preventive inoculations against tuberculosis in cattle, but the method was adjudged of sufficient merit to entitle him to the Nobel prize of $40,000 in 1901. Two years later he announced the extension of this prophylactic measure to the human infant, but this does not seem to have won acceptance by the medical profession, at least not so universally as his first great discovery. The discussion of the efficacy of this new method is, however, only in the academic stage, as yet, for the remedy will not be procurable for nearly a year, and until it has been extensively tried it will be impossible to determine its value.

The bold proclamation which Behring makes of his determination to keep his remedy secret so that he may reap the pecuniary rewards of his therapeutic discovery is reprehensible, but is in keeping with his previous acts. It will be remembered that in 1898 he secured a patent in the United States on the diphtheria antitoxin, and the chemists who made it for him served notice on physicians and manufacturers that any one using any but the patented Behring antitoxin would be prosecuted. The attempt to create a monopoly of this life-saving remedy failed, but through no fault of the greedy scientist. At that time there was an outburst of indignation in the press, both lay and medical, not only in this country but in Germany and throughout the world, which would have given pause to anyone with a thinner skin than Behring, but it apparently did not disturb him in the least.

If the remedy now announced should prove to be all that its discoverer claims for it as a certain preventive and cure of tuberculosis it will be interesting to note its reception by those who have conscientious objections to the use of secret remedies, or nostrums, whatever therapeutic value they may be shown empirically to possess. If they consent to employ the curative, but unethical, remedy, they must do violence to their principles; if they refuse, their patients will settle the question for themselves with deplorable disregard of the ethics of the case. But this is purely speculative and by the way, for we confess to much scepticism as to the validity of v. Behring's claims, and we fear T. C. will follow T. R. in the long procession of cures that fail to cure.

## THE ORIGIN OF CANCER.

The pathogenesis of cancer must still be acknowledged as belonging to the unsolved problems in medicine. Some perhaps may claim that this statement should be modified in the light of recent investigations, nevertheless, it may be quite truthfully said up to the present time no satisfactory answer has been returned to the question as to whether cancers and other neoplasms arise through a modification of the formative process or whether they are the outcome of an inflammation due to the intrusion and growth of specific microorganisms or to other external irritants. In other words, is cancer dependent upon an intrinsic or an extrinsic cause? The growing tendency of late years to ascribe most pathological processes to a germ infection, has rather overshadowed the older theories, but it still remains for the microbists to furnish more convincing proof of the truth of their claims than they have thus far done.

In the genesis of neoplasms as well as of all other organic structures, there are two factors to be considered, namely, the cells from which they are derived and the force which regulates this cellular activity. In a healthy body cell division proceeds until the organ is fully developed and then the process continues merely as a reparative one. There is a restriction to growth within certain bounds, but the guiding force may be affected by pathological conditions which inhibit its restraining influences and the cells continue to multiply in a lawless manner. We do not know the nature of this mysterious force, although some have ascribed it directly to the nervous system. An interesting, rather than convincing, article, in the form of a plea for this theory, has lately been published by R. H. Hodgson (*Medical Press*, August 9, 1905). He calls cancer a nerve disease with local manifestations, and claims that any specifically shaped bodies connected with it are the result rather than the cause of the disease. Moreover, he believes that the greater frequency of can-

cer in the later years of life is due to the fact that at this time the body has less reserve nerve force, all the tissues in his opinion being controlled by nervous influences, whether histologists are able to demonstrate the presence in them of nerve elements or not. The increase of cancer at the present time, he thinks, may also be explained by the greater demands now made on the brain and nervous system in general, which, having a greatly diminished reserve store of energy, is less able to resist long-continued irritation. According to Hodgson the true pathology of the condition will be cleared up only when we are able to obtain accurate chemical analyses of healthy nerve structures and can compare them both qualitatively and quantitatively, with those taken from the neighborhood of the disease.

The author's reasoning is ingenious, but is hardly logical enough to clear up the question. The "nervous wear and tear," which he and many others, are ever ready to accuse of numerous ailments with which man becomes afflicted, is not so universally prevalent among all classes of the population as we are led to believe, and those classes which might perhaps be placed in this category are not more frequently the subject of cancerous diseases than any others. The idea that some inherent force in the body initiates and governs the growth of neoplastic formations, is fraught with many elements of plausibility. But to assert that it is a force generated in the nervous system, would amount to the making of a claim which is not based on demonstrated facts. There is present in all living bodies a vital principle or force, still unknown and undefined as regards its character and laws, which governs growth and reproduction generally without the medium of such gross structures as may be represented by the nervous tissues, and it is to disturbances of this, that we may have to attribute some of the hitherto unclassified pathological processes, cancer among them.

## The Art of Cooking.

It may well be said that the development of the art of cooking is closely connected with the onward progress of the human race. As the prehistoric cave dwellers knew nothing of the uses to which fire might be put, their gastronomic abilities were probably on a par with those of the beasts of prey with which they competed for their daily supply of food. The earliest nations of whom we possess historic records recognized the value of foods properly prepared, and we find that the science of cooking gradually attained the height of its development during the reign of the great Roman emperors of the Augustinian period. We are apt to look upon the banquets of the old Romans as orgies, and in some senses they undoubtedly were, and yet we have abundant evidence that the Romans were cognizant of the fact that the proper preparation and seasoning of the food contributed, in large measure, to an improved appetite and a better digestion. We must therefore credit them with a knowledge of these physiological necessities, even while condemning them for their luxurious repasts. They also realized that a pleasant frame of mind had a great and important influence on the digestive processes and provided amusements of various kinds during the meal. The inroads of the northern barbarian caused the highly developed arts and sciences of the Romans, and culinary perfection must be included among them, to be plunged in a long period of darkness which marked the Middle Ages. Whatever knowledge we possess of their civilization, we owe to the many monastic orders of Europe, whose members preserved and cultivated, among other things, the traditions of the culinary art until the renaissance in the reign of Louis XIV. of France and his successors. The influence of France on the menus of the world has continued uninterruptedly down to the present day. The principles of cooking, speaking of the latter in a general sense, were developed by the early Romans in a purely empirical fashion. Now they have been made the subject of scientific investigation and found to rest on a firm and sound basis. The Russian physiologist Pavlov has clearly demonstrated, in his researches on digestion, that the ingestion of substances with a purely nutrient value does not sufficiently satisfy the demands of the body —taste and appetite must also be taken into consideration. These are satisfied only by the addition to the food of spices and salt, and it is largely due to the influence of these condiments that the proper amount of gastric juice is liberated by the mucous membrane of the stomach. The action upon the stomach of reflex stimuli is shown by the favorable effect on the flow of the gastric secretions made by mental impressions induced by the mere sight and odor of a well-prepared dish. In this manner, Epplen (*Reichs Medicinal-Anzeiger*, No. 18, 1905) leads up to the broad claim that the proper preparation of all food, as demanded by the essential requirements of the culinary art, is not a luxury, but a physiological necessity, and to develop and disseminate this knowledge is an act beneficial to the public welfare. There is happily an increasing interest taken by physicians in dietetics and cooking, for these two subjects go hand in hand, and this interest it should be the aim of the medical man to transmit to his patients, or to those who have care of them.

## Surgery and Etiological Research.

The advances of recent years in surgery have been no less notable in the scientific than in the technical direction. For the surgeon, as for the internist, the etiological factor in disease has come to occupy a place of supreme importance, and the results of investigations both on the operating-table and in the laboratory, have become apparent in the widening of the scope of the surgeon's work. Goebel calls attention to the practical influence of discoveries resulting from these investigations in an article in the *Allgemeine medizinische Central Zeitung* of August 19, 1905. In some instances, such as the introduction of antisepsis by Lister, the surgeon has been in advance of the establishment of the scientific truth that had served him as an hypothesis. But in this case, although asepsis and antisepsis have opened new fields for the surgeon in other directions, it has limited his work. The introduction of diphtheria antitoxin has resulted in reducing considerably the number of tracheotomies and of intubations, while the discovery of the selective action of tetanus toxin upon the cells of the nervous system, and of the toxemis, not bacteriemic, nature of the infection, has caused the abandonment of amputation in cases of tetanus. The establishment of the etiological factor in septicemia and pyemia and in osteomyelitis, together with Virchow's investigations upon embolism and thrombosis underlies the present treatment of such conditions by the wide opening of the abscesses to guard against the absorption of toxins and the spread of bacteria. To the surgeons themselves are due the discovery of the tuberculous nature of synovial infections, and the relations between bone and joint diseases. Tuberculosis as the cause

of peritonitis, is a discovery of the gynecologist. The successful treatment of this condition led to the conservative treatment of bone tuberculosis by iodoform injections. From the bacteriologist the surgeon learned the nature of gonorrheal infections of the joints, and from the internist the cause of certain bone abnormalities in syphilis, that are now less often the objects of surgical intervention. "Cachexia strumipriva" is but a name since the discovery of the functions of the thyroid, and a knowledge of the underlying condition in myxedema taught the surgeon the limits beyond which he might not go in his operations upon this organ. More recently the relation between tetany and the parathyroids has been determined, though this discovery can hardly be said to be of practical value as yet. The rôle played by appendicitis as the cause of many cases of peritonitis is another instance of the value of research in etiology. The study of carcinoma has resulted in the introduction of more radical therapeutic measures, and also prophylactic attempts, as in the early removal of gallstones that are now conceded to be an occasional cause of carcinoma of the gall-bladder. The basis of rational surgery lies in the discovery of the cause of the conditions to be treated. By the surgeon himself no less than by the bacteriologist, pathologist, and physiologist, our knowledge has already been increased, but much still remains to be accomplished.

## The Harvey Society.

There was given at the Academy of Medicine on last Saturday evening, the first of a series of lectures which served not only to introduce the Harvey Society to the medical profession of the city, but also as an inaugural of a movement which is worthy of support and commendation. In forming this society, its founders had in mind the gulf which seems to exist in medicine between the laboratory worker and the practising physician, but which is becoming happily narrowed by the efforts of organizations of this character. The enthusiastic reception accorded to the lecturer of the evening by a large audience representing both the biological and the clinical aspects of medicine, gives rise to the hope that the practitioner will continue to take an increasingly greater interest in the more purely scientific phases of medicine. As the lecture was given under the patronage of the Academy of Medicine, the proceedings were opened by the President, Dr. Chas. A. Dana, who in a few well chosen words dealing with the aims and objects of the Harvey Society, introduced Dr. Graham Lusk, the President of the latter, who in turn presented the speaker of the evening, Prof. Hans Meyer, of the University of Vienna. Prof. Meyer expressed his pleasure in being called upon to deliver the inaugural lecture of the course and, in commenting on the scope of the series, said that the movement, not only to him, but to his colleagues in Europe, constituted one of the evidences of the lively interest taken by American physicians in the abstract problems of medical science. The subject of the evening's discourse, "Die Theorie der Narcose," is one with which the lecturer is particularly identified, having done a great deal of experimental work dealing with the manner in which narcotic drugs affect the system. His theory is that there are many indifferent substances which exert a narcotic effect, or do so in combination, if they possess the power of dissolving fat, this seemingly constituting the essential requirement for narcotic action. The second lecture, entitled "The Modern Problems of Metabolism," will be delivered by Prof. Carl v. Noorden of Frankfort, on this Saturday evening, October 14.

# News of the Week.

**The New York State Medical Association.**—The twenty-second annual meeting of this Association will be held at the New York Academy of Medicine on October 16-19, 1905, under the presidency of Dr. J. Riddle Goffe. Among the subjects for discussion announced on the program are a symposium on hygiene and preventive medicine, one on the toxemia of pregnancy, one on the non-surgical, and another on the surgical treatment of cancer. The annual dinner will be at the Hotel Astor on the evening of Wednesday, October 18. A committee of ladies has been organized to provide entertainment for the wives and daughters of visiting members. There will be a tea in the reception room of the Academy on Monday afternoon, an automobile drive on Tuesday afternoon, and a steamboat excursion around Manhattan Island on Wednesday afternoon. The chairman of the committee of arrangements is Dr. Frederic W. Loughran, the secretary of the Association, Dr. Charles Ira Redfield of Middletown.

**Army Health Report.**—According to the annual report of Surgeon-General O'Reilly there has been a steady improvement in the health of the army during the year ending June 30. In this period there were 406 deaths from all causes, or 6.75 a thousand, as compared with 8.64 for the previous year and 17.93 for the years 1898-1902. The percentage of men constantly non-effective also showed a material decrease. Pneumonia was the greatest cause of death, the rate per thousand being 0.65. Tuberculosis was second with 0.37 and typhoid fever next with 0.33. The Engineer Corps had the highest rate per thousand for disease, the cavalry next and the Ordnance Department the lowest. For death rate from disease the Signal Corps stood the highest. Regarding typhoid fever Fort Leavenworth, with fifty-three cases, led all army posts and reservations. The outbreak of beriberi among the Philippines scouts at the St. Louis exposition resulted in fifty-nine cases, four of which were fatal. There was but one case of yellow fever reported, at Fort Brown, Tex. At Fort Stevens, Ga., there is a case of leprosy, the only one in the army. During the year there were 206 cases of gunshot wounds, 44 of which proved fatal. Twenty-one men were killed in action, 45 were drowned, 27 committed suicide, and 10 lost their lives through homicide. Among the native troops in the Philippines, 56 enlisted men were killed and 25 wounded. The unusual proportion of killed to wounded, there being fewer wounded than killed, is explained by the fact that 47 of the killed were victims of hand-to-hand fighting with edged weapons.

**Alleged Extravagance in the Marine Hospital Service.**—It is stated that as the result of his investigations regarding the Marine Hospital Service, Secretary of the Treasury Shaw has decided to recommend the abandonment of eleven of the twenty-three hospitals maintained for that service by the government. It is alleged that the Marine Hospital Service is costing the Government twice as much as it did a year ago. As the result of his investigations Mr. Shaw has concluded that the whole system of contracting for the care of sick sailors should be reorganized and that in several places the marine hospitals now maintained at Government expense should be abandoned. In some instances he thinks it would be much more economical for the Government to make a contract with local hospitals for the care of sailors than to maintain a separate establishment at Fed-

eral expense. It is, of course, desirable that the expense of the Public Health and Marine Hospital Service be kept as low as is compatible with the efficiency of the service, but it would be a lamentable error to cut down the appropriation to such an extent as to cripple the work, especially in its relation to the public health. The good accomplished by Dr. White and other surgeons of the Marine Hospital Service in New Orleans is too fresh in the public mind to make a niggardly policy popular. It would never be wise or right

**American Association of Railway Surgeons.**—The second annual meeting of this association was held in Chicago, October 4, 5, and 6, 1905 under the presidency of Dr. John E. Owens of Chicago. Forty papers were read, most of them being freely discussed. One session was taken up in discussing the care of fractures; conservative treatment of compound fractures; wiring as a means of securing the best results in compound fractures of the long bones; direct fixation in fractures; fractures of the vertebral column involving the cord and its treatment; fractures of the spine: Colles' fractures; fractures of the patella and fractures of the leg. An interesting feature of the meeting was a lantern-slide exhibit of anopheles and stegomyia mosquitos, with remarks on how freight and passengers are handled from the quarantined city, New Orleans, by Dr. L. Sexton, of New Orleans. Dr. John B. Murphy of Chicago gave an interesting and instructive talk on the relations of trauma to bone tuberculosis. The following officers were elected for the ensuing year: *President*, Dr. Richard W. Corwin, Pueblo, Col.; *Vice-Presidents*, Drs. J. H. W. Meyer, La Porte, Ind., S. L. McCurdy, Pittsburg, Pa., Bacon Saunders, Fort Worth, Tex.; *Secretary*, Dr. H. B. Jennings, Council Bluffs, Iowa; *Treasurer*, Dr. T. B. Lacey, Council Bluffs, Iowa; *Editor*, Dr. Louis J. Mitchell, Chicago, Ill.; *Members of the Executive Board*, Dr. W. S. Hoy, Wellston, Ohio. and Dr. J. R. Hollowbush, Rock Island, Ill. The time and place of the next annual meeting were left to be decided by the Executive Board.

**An Appeal for Unity.**—The following appeal has been sent to all the members of the New York State Medical Association, urging them to vote at the coming meeting for union of the two State medical organizations: "At the approaching annual meeting the opportunity will be presented for us to take definite and final action in consummation of the amalgamation agreement between the two State medical organizations. Our officers have arranged a method of procedure in accordance with the requirements of the law and the dictates of the Courts. There is nothing now to prevent union except indifference on the part of members of the Association. We therefore appeal to all members of the Association who have at heart the best interests of the medical profession of our Empire State to attend the business meeting called for 10 o'clock, Tuesday, October 17, and to come prepared to express their wishes, by ballot, in no uncertain way, in support of every act and resolution favoring the union between the two State medical bodies." This appeal is signed by Drs. Charles G. Stockton, De Lancey Rochester, Robert Abbe, W. Gilman Thompson, Reginald H. Sayre, John A. Wyeth, Francis J. Quinlan, Herman J. Boldt, A. J. McCosh, Edward G. Janeway, A. A. Smith, James P. Tuttle, Chas. Stedman Bull, D. Bryson Delavan, W. M. Polk, Joseph D. Bryant, and John F. Erdmann.

**New York's Death Rate.**—According to the latest report of the Board of Health New York City now has a lower death rate than has been recorded before in over a hundred years. The report covers a period from January 1 to June 30, 1905, and shows that the death rate has diminished from 22.24 per cent. to 19.23 per cent. per 1,000, as compared with the corresponding period last year. This calculation is made on an estimated population of 3,938,000. The census returns of the Department of Health indicate a much larger population, which will give a crude death rate of about 18 and a corrected rate of a little over 17, the lowest recorded since 1798. The records of the first six months show these comparative figures: 1905—Births, 50,943; marriages, 20,768; deaths, 42,690. 1904—Births, 47,384; marriages, 19,295; deaths, 37,969. It is further stated in the report that more than nineteen thousand quarts of adulterated milk were destroyed, and nearly $10,000 collected in fines for violations of the law against milk adulteration. Over 4,000,000 pounds of fruit, 7,500,000 pounds of food, and 1,000,000 pounds of meat and fish were condemned and destroyed.

**Yellow Fever in the Southern States.**—The reports from the infected regions continue to be very encouraging. This is particularly the case in regard to New Orleans where the death rate from all causes during the past week was only 18 per 1,000, which is lower than ever before. Apparently the epidemic has not been an unmixed evil, since it has caused sanitary conditions to be improved to a degree undreamt of before, and it is not likely that any relapses will be permitted. At Vicksburg the total number of cases has reached the neighborhood of 150. Some of the smaller places such as Pensacola, Fla., Hamburg, Miss., Scranton, La., and Pascagonla, La., are still in some danger, however, owing to the obstinacy of the people in refusing to take the precautions urged by the sanitary authorities.

**Plague Village Burned.**—In order to prevent spread of the bubonic plague from the Mongolian village of Dalai-Nor, situated near the Russian frontier, the inhabitants have been transported to a quarantine station some distance from the railway and the village has been burned. Troop trains bearing soldiers returning to Russia have been forbidden to stop at the station.

**Another Ambulance Accident.**—In what is the ninth ambulance accident occurring in Brooklyn since the beginning of the summer the horse was killed and the ambulance smashed. The accident was caused by the collision of a Smith Street trolley car with a Flatbush Hospital ambulance.

**American Public Health Association.**—At the closing meeting of the five-days session of the thirty-third annual convention of the American Public Health Association held in Boston September 25 to 29, it was decided to hold the next annual meeting in the city of Mexico. The following officers were elected: *President*, Dr. Franklin C. Robinson of Brunswick, Me.; *Vice-Presidents*, Dr. Joseph J Kinyoun of Pennsylvania, Dr. Domingo Orvananos of Mexico, and Dr. Richard H. Lewis of North Carolina; *Treasurer*, Dr. Frank W. Wright of Connecticut; *Executive Committee*, Dr. Juan Guiteras of Cuba, Dr. H. L. Russell of Wisconsin and Dr. William C. Woodward of Washington, D. C.

**Medals from the Anti-Tuberculosis Association.**—At a meeting of the International Anti-Tuberculosis Congress in Paris last week the committee on awards bestowed a gold medal on Dr. Brouardel and silver medals on Drs. Bang of Copenhagen, Biggs of New York, Broadbent of London, and Schroeder, of Vienna.

**Typhoid Fever in New York State.**—At the fifth annual conference of the health officers of the State held in Albany on October 4, Dr. Eugene H. Porter, State Commissioner of Health, said that since January 1 there had been the enormous number of 60,000 cases of typhoid fever in this State, with 500 deaths from this cause in Greater New York alone. He said an increasing volume of sewage was pouring into the streams of the State, and that practically all of them were contaminated, while many were little better than open sewers. He declared that while filtration plants were excellent, they were not sufficient to prevent typhoid, and he insisted that the continued pollution of streams and lakes must stop. He further stated that it was the intention of the Department to begin a systematic investigation of the various summer resorts and to institute the necessary reforms at these places.

**Diphtheria Among Insured Children.**—The circumstances attending the deaths of some of the many children succumbing to diphtheria in South Chicago recently led the Health Commissioner to make a special study of the conditions in that neighborhood. It was found that life insurance agents have been doing an extraordinary business in risks on children in the district. In a majority of the cases the children were insured for $300.

**Investigating the Bakeries.**—At a recent inspection by the Health Department of the bakeshops in New York City, thirty three were found in bad condition and in twenty-two immediate changes were ordered. At the time of the recent strike among the union bakers so much was said about the unsanitary condition of some shops and the prevalence of tuberculosis among bakers that the Department made an examination. It was found that the number of consumptives among the bakers is surprisingly small, instead of being large, as alleged.

**Poisonous Cosmetics.**—The State Board of Health of Indiana has decreed that cosmetics shall hereafter bear the skull and crossbones as a warning that they are poisonous, otherwise their sale will be illegal in Indiana and the seller will be arrested. H. E. Barnard, the State chemist who has been making an investigation of these preparations, says that practically all of them contain corrosive sublimate and that the State laws require that no poison shall be sold unless it is designated as such.

**Cholera in Europe.**—Two more cases of cholera have been reported in Prussia, making the total 261 cases and 89 deaths. According to the report of the Pest Commission, on September 29 and 30 twenty-one new cases of cholera were discovered in Russian Poland, and during the same period there were nine deaths from the disease.

**Yellow Fever at Panama.**—Since September 15 but two cases of yellow fever have been reported from the Canal Zone. No cases have occurred since September 20, and during the entire month of September there were nine cases seven of which were among foreign non-employees.

**Tri-State Medical Society.**—At the last session of the Tri-State Medical Society of Tennessee, Georgia, and Alabama, held at Chattanooga on September 28, the following officers were elected. *President*, Dr. A. B. Cooke of Nashville, *First Vice-President*, Dr. W. D. Haggard of Nashville, *Second Vice-President*, Dr. A. A. Davidson of Augusta, Ga.; *Third Vice-President*, Dr. W. P. McAdory of Birmingham, Ala.; *Secretary*, Dr. Raymond Wallace of Chattanooga; *Treasurer*, Dr. George R. West of Chattanooga.

**Contract Practice.**—We are informed by Dr. Ernest Brown, Chairman of the Executive Committee of the Peterborough (Ontario) Medical Association that twenty-five out of twenty-six medical men in Peterborough signed the agreement to refrain from contract practice. Although the absence of the one signature rendered the agreement invalid, the condition was not one with no approach to unanimity, as had been stated.

**Cedar Mountain Sanatorium Reopened.**—After having been closed for many months, because of lack of money for its support, the Cedar Mountain Tuberculosis Hospital, annex to the Hartford Hospital, was again open for the reception of patients on October 2. This was made possible through an appropriation made by the last general assembly and through contributions from the residents of Hartford. The physicians who are directly in charge of the annex are Drs. Walter R. Steiner, Robert S. Starr and Henry F. Stoll.

**Diphtheria at Annapolis.**—The epidemic at the Naval Academy appears to be well under control, for the authorities have announced that there have been no new cases for four days. Many of the patients are entirely well, and it is expected that the academy will open on October 14.

**Foundling Home for Cleveland.**—John D. Rockefeller has promised to erect a $50,000 building to be used as a foundling home by the Cleveland Humane Society.

**American Academy of Medicine.**—The Thirtieth annual meeting of the American Academy of Medicine will be held at the Assembly Hall of the Northwestern University Building, corner of Lake and Dearborn Streets, Chicago, on Thursday, and Friday, November 9 and 10, 1905

**The Typhoid Epidemic at Nanticoke, Pa.**—The outbreak of typhoid in this town continues with unabated violence, and there are now over four hundred cases. The ministers of the town have united for the purpose of holding a series of meetings, one in each church, to pray for relief.

**For New Jewish Hospitals.**—At a recent hearing before Commissioners William Rhinelander Stewart and Dr. Stephen Smith, of the Eastern Inspection District of the State Board of Charities, applications for charters for new Jewish hospitals to be built in the lower East Side were made by six different organizations. These were the Columbus Dispensary, the Zion Hospital Association, the Carmel Hospital and Dispensary, the Jewish Hospital for Deformities and Joint Diseases, the Beth Jacob Joseph Hospital, and the East Side Hospital Association. As in most instances the projects of the different applicants were still in the rudimentary stage, and, especially as very little money had been pledged in their interest, the commissioners advised them to attempt to effect a consolidation, and stated that while it appeared that there was a demand for more hospital accommodations in that part of the city, six new charters would certainly not be granted.

**New Use for Carnegie Gift.**—The trustees of the fund of £500,000, yielding a yearly income of £25,000, which Andrew Carnegie presented to his native city of Dunfermline, have been hard put to it to spend their income. Various schemes for providing the people with musical and artistic facilities of high order have failed to meet with popular approval, and the latest plan has been the establishment of a College of Hygiene and Physical

Training. This is intended to foster the development of physical training among the young people, and to supervise the study of hygiene in the public schools. The college was formally opened on October 4.

**Tuberculosis in Prussia.**—A remarkable decrease in the number of deaths from tuberculosis in the larger cities of Prussia within the last two decades is recorded. In 1896 the death rate in cities of over 100,000 inhabitants was 37.36 per 10,000; in 1902 it was only 22 per 10,000.

**Medical Society of Virginia.**—The thirty-sixth annual session of this society will be held in the Young Men's Christian Association Building, Norfolk, on October 24–27, 1905, under the presidency of Dr. William S. Christian, Urbanna.

**Civil Service Examinations.**—The State Civil Service Commission has announced a general examination to be held on October 28. Among the positions included in this examination are those of Assistant in Botany, Education Department, $600; Assistant in Microscopy, Buffalo Cancer Laboratory, $720. The last day for filing applications is October 23. Application forms and detailed information may be obtained by addressing the Chief Examiner of the Commission at Albany.

**Dr. W. A. Dickey** of Toledo has resigned as Dean and Professor of Medicine at the Toledo Medical College.

**Dr. Clyde I. McKinniss** of Marion, Ohio, has been appointed Assistant Physician to the Columbus State Hospital for the Insane.

**Dr. J. D. Dunham** of Columbus, Ohio, has resigned as Professor of Bacteriology at Starling Medical College and has been appointed Lecturer on Diseases of the Stomach.

**Dr. John K. Scudder** of Cincinnati has been reappointed by Governor Herrick as a Member of the State Board of Medical Registration and Examination.

**The Toledo Medical College** has become the Medical Department of the Toledo University.

**The East Side Physicians' Association.**—The next meeting of this society will be held Friday evening, October 20, at 67 St. Marks Place. Papers will be read by Drs. Brodhead, Von Ramdohr, Huber, and Silver.

**Diphtheria.**—The public schools around Farmington and Green Township, Livingston Co., Ill., have been obliged to close, owing to the prevalence of malignant diphtheria.

**Chicago Deaths During the Week.**—The total deaths from all causes numbered 512 during the week just ended, this being equivalent to an annual rate of 13.4 per one thousand of population. Acute intestinal diseases led, causing 114 deaths. Consumption came second, showing a mortality of 51; heart diseases, 47; violence, including suicide, 41; Bright's disease, 30; and pneumonia and nervous diseases, each 24.

**Hospital Site in Oak Park (Ill.).**—The Oak Park Hospital Association is still determined to have a hospital, to cost $100,000 or $150,000, although at the last election a number of people voted against it. At a meeting recently held, Dr. J. W. Tope submitted a proposition to the executive committee of the hospital association to pay for the site selected for the institution. This site is situated in Fair Oaks, in the northern part of Oak Park, and consists of six acres.

**A New Building for the Chicago Policlinic** will be built at the southeast corner of Oak Street and La Salle Avenue. The new structure is to be six stories high, and will be thoroughly modern in the equipment of all departments.

**A Government Hospital at Illiopolis.**—An option on 640 acres of land at Illiopolis, Ill., has been secured by Dr. L. Declermont, of Washington, D. C. On this land the United States Government contemplates building a hospital for the army and navy. It will have a capacity of 3,000 patients. It is expected that the Illiopolis authorities will furnish lighting facilities and water supply.

**A New Maternity Hospital in Chicago.**—Land has been secured on the south side, and a maternity hospital, thoroughly modern and perfectly equipped, is to be constructed at once. The plans are under way. The men's board of the Lying-In Hospital has pledged itself for the necessary money, and in order that it may be left free to attend to this, the woman's board has agreed to raise $8,000 to complete the funds for the running expenses of the present hospital for the current year. This will be done by public subscription.

**Obituary Notes.**—Dr. Wilson T. Bassett died at his home in Cooperstown, N. Y., on October 3, at the age of eighty-four years. He was a graduate of the Albany Medical College, class of 1844.

Dr. John O. McReynolds of Elkton, a well-known physician of Kentucky, died on October 6, at the age of seventy-eight years. He was graduated from the Jefferson Medical College in 1849.

Dr. Arthur Weir Johnstone of Cincinnati, died at his home on Madison Road after a week's illness from appendicitis. He was one of Cincinnati's best known surgeons. He was fifty-two years of age and was born in Danville, Ky. He was graduated from the New York University Medical College in 1876.

Dr. Decatur Curran Anderson of Moss Point, Miss., died on September 28 at Tallulah, La. He went to that place in company with several other physicians to assist in fighting the yellow fever, but contracted the disease himself and died within a few days. Dr. Anderson was a graduate of Tulane Medical College.

Dr. P. J. Kirschner of St. Joseph, Mo., died on September 22 at the age of fifty-two years. He had been in poor health for three years and his condition had been serious for some time. He was graduated from the Bellevue Hospital Medical College with the class of 1879, and at various times occupied several public offices in St. Joseph, including the mayoralty.

---

## Correspondence.

### OUR LONDON LETTER.

(From Our Special Correspondent.)

SIR VICTOR HORSLEY ON VERTIGO—DEATH OF DR. T. J. BARNARDO, F.R.C.S., EDIN.—PRECAUTIONS AGAINST CHOLERA—SIR THOMAS BROWNE'S STATUE—MR. JONATHAN HUTCHINSON'S COMING BOOK—ASYLUMS BOARD.

London, September 22, 1905.

The pathology of vertigo interests both general and special practitioners, and the views of Sir V. Horsley, which were lately expressed before the Otological Association, deserve careful consideration. His experience was principally drawn from two classes of patients (*a*) destructive ear disease, (*b*) new growths, though he had of course seen numerous cases of Ménière's disease. He defined severe vertigo as a sudden disturbance of equilibration, and said what we want to know is whether that disturbance occurred in the periphery, *i.e.* in the semicircular canal, and whether such disturbance in the periphery is produced by pressure in the middle ear, on the labyrinth, or by direct disease of the labyrinth. Then we want to know whether the mischief is in the trunk of the vestibular nerve, or in the bulb, or in the cerebellum, or in the pons, or in the crus, or finally in the cortex, and particularly that of the temporal lobe. He alluded to the question whether the faculty of orientation in space is represented in the cerebrum, and suggested that it was principally in the temporal lobe. Sir Victor regarded vertigo as a physiological phenomenon,

strictly analagous to the onset of an epileptic fit or of trigeminal neuralgia. Such a sudden physiological disturbance of the central nervous system as that in severe vertigo could only be analagous to a condition of things in which there was a summation of stimuli. To begin with, the peripheral mechanism cases of semicircular canal disease require most attention in the direction of localization. More minute localization of peripheral disease would furnish the groundwork of more correct localization of central disease. He had not seen true vertigo from disease of the vestibular nerves except in cases of new growths. As to the medulla itself, the difficulty of localization between the eighth nerve and medulla itself was that in all cases of eighth nerve implication, the region of the auditory striæ and Luschka's lateral recess was the usual situation of new growths. He suggested further that true rotation, *i.e.* objective rotation, forced movement does not occur from simply middle ear trouble. The forced movement did not occur until the vestibular trunk or the wall of the labyrinth was implicated.

Passing to the cerebellum, he said it contained two distinct organs, the lateral lobe and the vermis. The latter was concerned with rotation round a horizontal plane of the body; the former round the vertical axis. From either of these might occur the rotation of a vertigo, the localization of which was comparatively precise. The lateral lobes of the cerebellum were not directly united with the cerebrum, but were connected by the middle peduncle with the pons and this with the temporal lobe. Sir V. Horsley demonstrated by lantern photos the strictly localized lesions and clinical phenomena caused in rabbits shot while running away. A photo of a rabbit's brain in which a single pellet passed through the petrosal portion and superficially through the tip of the temporal portion of the hemisphere was shown. The animal, when hit, sprang into the air and had typical rotation fits around a longitudinal axis; it had skew deviation, right eye directed downwards and contracted pupil, left upwards and dilated pupil, limbs of opposite side rigid—all the phenomena of a middle peduncle lesion. Another photo showed forced movement of rotation from a bruising of the pons. The rabbit lay unconscious in the cerebellar attitude, fore legs rigidly extended, head drawn to the right, with that leg semiflexed and the left fully extended. No shot penetrated the brain, but one had fractured the petrous bone and slightly bruised the middle peduncle of the cerebellum and trapezium. The case of a boy who fell on his head from a see-saw was described. He had vertigo and auditory amnesia from a lesion of the middle peduncle of the cerebellum. In any given case of vertigo a differential diagnosis of the seat must first be sought in the direction of the forced movement, then functional cases must be excluded and next a complete examination of the central nervous system made.

As to treatment, Sir Victor said in middle-ear cases the bone and mucous membrane must be treated by ordinary surgical rules. As to Ménière's disease when congestion of the semicircular canals had been diagnosed and the cases sent to him with a view to division of the eighth nerve, although willing to operate, he had not yet done so, but had advised previous treatment, but he did not know whether that had been successful, as the patients did not return to report. As to central disease, the cases almost always were due to new growth, and the only treatment removal.

Dr. Risien Russell at the same meeting considered vertigo from the medical aspect as a subjective sensation of movement, whether accompanied by actual movement or not; or a sensation that surrounding stationary objects were in motion, and the term was sometimes applied to a vague state of light-headedness without a definite sense of displacement of the body or surrounding objects.

Dr. T. J. Barnardo died on Tuesday morning at the age of sixty, after forty years of strenuous philanthropic work, which has made regret at his loss universal. The King and Queen both sent messages of sympathy, and the poorest of the East End people know they have lost the friend of the homeless children. Thos. John Barnardo was a London Hospital student. He entered there with a view of qualifying as a medical missionary, but was diverted from his purpose by what to many might seem an accidental circumstance. In the cholera epidemic he worked hard with some other students; they made a house-to-house visitation, and there he saw much of slum life. Afterwards, with the others, he carried on a Sunday and ragged school in a donkey stable, where, one night, a wretched waif begged hard to be allowed to sleep. Finding this boy had no father, no mother, no home, was simply a street Arab, without any regular sleeping place, he asked if there were other boys in the same state, and was answered "Oh, yes. 'eaps on 'em, more'n I can count." To ascertain the truth of this he got the boy, after feeding him, to take him where he could see these "'eaps" who "didn't live nowheres," and that night he resolved to devote his life to help the helpless, and from that time we may date the commencement of the National Institution for Waif Children. With faith and courage which never failed, he took a little house to provide for a few boys, and the work has grown under his guidance until at the close of last year there were 7,078 children being maintained in the homes under his care. In addition, 120,239 free meals, 31,032 free lodgings, and 92,533 garments were distributed to boys and girls in the year. No doubt, as has been said, he was a wonderful organizer, but there was something more than that in the capacity and success which have made his work seem such a romance. He did not altogether escape opposition and harsh criticism, but they could not hinder the success of his methods, as one fact proves, out of 16,000 children educated and emigrated to the colonies, less than 2 per cent. have been failures. He "rests from his labors and his works do follow him."

The Newcastle authorities are naturally anxious about cholera. They have appointed three medical men to assist Dr. Hooper, their medical officer of health. He has arranged for a continuous medical service, so that every vessel arriving in the Tyne from any North Sea port will be boarded. Two or three suspicious cases have arrived, but so far the disease has not obtained a footing.

The arrangements for unveiling the statue of Sir Thos. Browne are complete, and the ceremony is to be performed on the four hundredth anniversary of his birth (October 19), by Lord Avebury.

Mr. Jonathan Hutchinson is about to publish a volume on leprosy and fish eating, in which it is to be presumed he will embody some account of his tours in South Africa and India, and his latest opinions as to prevention.

The Asylums Board has appointed a committee to investigate the causes of the resignation of three assistant medical officers of their asylums, which I reported to you, so it is to be hoped the dissatisfaction which has long existed among their medical officers may be investigated and removed.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

MANILA, P. I., September 1, 1904.

CHOLERA has again made its appearance in the city of Manila. On August 23, at an autopsy held upon a prisoner who died in Bilibid Prison, the intestines were found to be much injected, with a rice-water material in them, and the solitary follicles and Peyer's patches were found enlarged and swollen. The case was considered very suspicious, and specimens were at once taken to the Government Laboratories for bacteriological examination. On August 25 the director of the laboratory, Dr. Richard P. Strong, reported that the cholera spirilla had been found in the specimen submitted. Suspicious cases have been reported from time to time for some weeks past, but careful autopsies and bacteriological examinations failed to show any Koch's spirilla present. It therefore came as a matter of surprise that cholera should be detected in a prison which is so well guarded against the introduction of improper food substances, and especially so in view of the fact that no cholera has been reported in the Philippine Islands since April, 1904. Soon after the case in Bilibid was reported, information was received that at Fort McKinley a number of soldiers were stricken with a disease, the symptoms of which very much resembled cholera. There were seven cases reported, two of which had died, presumably from acute alcoholic poisoning. Two more men were stricken soon afterward; they died, and the bacteriological examination revealed Koch's spirilla. Fort McKinley was immediately placed in quarantine, all suspicious food stuffs were destroyed, and the soldiers were requested to take every precaution against contracting the disease. Up to the present writing no further cases have occurred in the Fort. In all there have been nine cases and four deaths.

On August 25 there were two Americans stricken with the disease, who died in a few hours. In one of the subjects almost pure culture of the cholera spirilla were found. The cases up to the present time have been of the most virulent type, and take the form ordinarily described as cholera sicca.

Since the first victim, the number of cases in Bilibid has been steadily increasing, until it has been reported to-day that there are some twenty-four or twenty-five cases in all in that institution. Cholera has been present in Manila for ten days, and the total number of cases has been about fifty-one. It will therefore be seen that fully one-half of the cases occurred in Bilibid Prison. The medical authorities of the prison have been at a loss to understand how the infection has been propagated.

Up to the present time there seems to be no positive information as to just how cholera entered the city of Manila. In view of the fact that cholera was reported in Hong Kong some weeks ago, it was at first thought that it was being

introduced from China; but later information points to the fact that cholera was in the interior of Luzon at least one week before any cases made their appearance in Manila, and there is every indication that the disease reached Manila from Laguna de Bay by the Pasig River.

From the foregoing, it would appear that cholera is endemic in the Philippine Islands, and that whenever the conditions are favorable the disease probably assumes an epidemic form. Including the cases in the provinces and those in Manila, there have probably been one hundred in all.

The work of the health authorities has been very much hampered by the fact that within the last few days the natives have commenced to hide the cases, and for that reason it has been impossible to disinfect the premises in which cases occurred. If this practice continues, there will no doubt be many foci of infection, and it is difficult to see how the disease can be checked before great loss of life results.

## PNEUMONIA AND MOUTH BREATHING.

To the Editor of the Medical Record:

Sir: I have read with much interest your editorial of September 16, and, having read the preliminary report of the Pneumonia Commission, I agree with you that it is not at all satisfying, "and there is not to be found here much promise of a speedy reduction of the shameful mortality from pneumonia in our Northern cities." The experience of four years' work along the lines covered in my monograph "Mouth Breathing" prompts this letter, and I assure you that if your readers become nasal breathers, and see that their patients also become such, they will do much toward stamping out, not only pneumonia, but all diseases of the respiratory and adjacent tracts. To resist affections of the respiratory and adjacent tracts, man must have a breathing apparatus free from obstruction and irritable areas. The normal breathing tract will not remain unaffected if long dry. When does the respiratory tract become dry? When the individual breathes with open mouth. This is certainly true, and may occur in any section of the upper breathing tract, and I believe a normal and physiologically moist upper breathing tract is pollen and germ proof. If this is true for the upper respiratory sections, why is it not true for the lower? It is not necessary that the individual be an habitual mouth breather to possess dry respiratory areas. Ofttimes a few moments of ordinary conversation will occasion this if he is not careful to take the air as he requires it through the nose. To properly filter, moisten, heat, or cool inspired air, to properly aërate the blood, and dilate the lungs throughout, one must breathe through the nose. The breathing tract of the normal breather is not a soil for bacilli. Can this be said of the breathing tract of the mouth breather?

Who is best prepared to resist pneumonia and other respiratory affections, the well-clad individual in the street on a cold winter's day, with his mouth open, or his friend who walks beside him, equally well clad, breathing as nature intended he should? Common sense teaches that the former is liable to infection. Again, who is most liable to respiratory affections, the individual who can expand his chest four inches, and does it a few times every day, and never breathes through his mouth, or he who expands his chest but one and one-half to two inches, or four if you will, and is a mouth breather? Who is most liable to an irritable throat, he who, while preaching or singing, takes his air through his nose as he requires it, or one who takes his air through his mouth? Who is most liable to spasmodic croup, the child lying in his crib with his mouth open, or the child by his side with his mouth closed? Who is most liable to pulmonary tuberculosis, the doctor in a tuberculosis hospital ward, who goes from bed to bed, breathing faultily, or his colleague, who breathes through his nose at all times? One need not be a physician to intelligently answer these questions. Who is going to make the speedier recovery, the nasal breather, who, through some indiscretion, contracts an affection of his breathing tract and continues a good breather, or the mouth breather, similarly affected, whose faulty breathing is allowed to go on uncorrected? I unhesitatingly say the former, for I am daily proving its truth.

To know what it is to be a nasal breather, to know what it is to resist, or to feel that one can resist at all times, respiratory affections one must have breathed through the nose for at least a few days normally. It is a comfort in going to sleep to know that the lips are going to remain in apposition the entire night, if for no other reason than the assurance that, on awakening, one's mouth is moist and clean. The plaster mouth-guard, as advised in "Mouth Breathing," is most satisfactory. We will have accomplished much when the time comes, and it is surely coming, when not only adults, but children, shall appreciate that if they do not use the nose at all times they are liable, not only to all forms of respiratory affections but to a large percentage of aural and eye troubles.

W. H. FitzGerald, M.D.

Hartford, Conn.

## CAPITAL PUNISHMENT.

To the Editor of the Medical Record:

Sir: The letter on "Capital Punishment" by Dr. Castelli of New York, in a recent issue, strikes the keynote of humanity. The present method of capital punishment used in our country belongs to the period of barbarism. As shown by the statistics of crime, it has failed to accomplish that which our forefathers intended. As stated by the paper, it punishes not only the guilty, but his friends and relatives. I hope to see the day when the people of my nation will feel that every man is his brother's keeper, and if we must free the nation of its criminal element, let it be done in at least as humane a method as was employed by Greece or Rome. James W. Riley strikes a truth in his "Doc Siphers" when he asks who is to pull the rope for the twelve sound-minded jurymen after they pull the rope for the unbalanced, pitiable wretch who has taken the life of one of his fellowmen.

We all know that a mother or father of criminal tendencies transmits them to the offspring. Of course this propagation of criminals must be stopped for the benefit of future generations, and this can be done only by effective legislation; but the surety not the severity of punishment is what brings results. Parents who punish their children at times without parental feeling and then allow them to run rampant, do not have good, obedient children. Neither will a nation by severe and barbarous punishment, obtain results. Only when punishment is reasonable, just, and absolutely sure shall we begin to overcome the ever-increasing tendencies to crime in this our beloved country.

J. T. McDavid, M.D.

Decatur, Ill.

# Progress of Medical Science.

*The Boston Medical and Surgical Journal, October* 5, 1905.

**Vertigo of Aural Causation.**—Clarence J. Blake, reviewing the subject of the aural causation of vertigo, concludes as follows:(1) In view of the existin knowledge of normal conditions in the semicircular canals, vertigo of aural causation may be regarded primarily as a pressure symptom. (2) Pressure may be exerted upon the labyrinth by forces operating from without, as the result of changes in the middle-ear transmitting apparatus. (3) It may be produced from within by invasion of the intracapsular space, as in the case of hemorrhage into the labyrinth. (4) The effect upon the semicircular canals, of intralabyrinthine pressure thus produced will depend, as to its intensity and duration upon the locality and extent of the hemorrhagic invasion. (5) Recurrent vertigo is the result of an excessive intralabyrinthine vessel dilatation, from suspense of vasomotor inhibition of reflex origin, either alone, or coupled with a persistent intralabyrinthine pressure, of either extrinsic or intrinsic origin.

*New York Medical Journal, October* 7, 1905.

**Modification of the Guaiac Test for Blood.**—The preliminary note made on this subject by I. S. Wile, consists in the extracting of the coloring matter from a suspected source and testing for the hemoglobin at one step. The technical procedure is thus outlined: To equal parts of chloroform and turpentine tincture of guaiac (U. S. P.) is added, a drop at a time, until slight milkiness appears. To one or two cubic centimeters of this reagent the suspected solution is added and the mixture is thoroughly shaken. In the presence of blood the chloroform-turpentine-guaiac solution becomes blue. The color takes a few seconds to manifest itself, but gradually deepens until all the hemoglobin has entered into the reaction. The color then gradually becomes lighter and slowly disappears. The triple mixture above described, will keep for several days without losing its power to give the reaction, provided it is stored in an amber-colored bottle. If desired, a ten per-cent. solution of resin of guaiac in glacial acetic acid, and may be substituted for the tincture.

**Shock and Hemorrhage as Causes of Death Following Abdominal Operations.**—The paper of C. C. Barrows is based on the statistics of a hospital service, in which twenty-five deaths occurred from all causes in five years, four of these having been due to shock and one to secondary shock, following hemorrhage. The author finds

among authorities a practical unanimity as to the causes, diagnosis, and treatment of this condition. The author notes that in hemorrhage, as a rule, the patient regains consciousness promptly from the anesthetic, is extremely restless with a panting respiration from lack of oxygen, there is great thirst and a sense of impending danger. In shock, on the other hand, the patient lapses with greater or less rapidity into a condition of semi-coma or into coma without restlessness, or expressions of much bodily discomfort. The breathing is, as a rule, shallow and less rapid than in hemorrhage. A valuable prophylactic measure is the intravenous injection of a normal saline solution just before operation. The surgical work should be done as quicky as is consistent with accuracy, so as to lessen the duration of the anesthesia. The use of rubber gloves is commended as being far less irritating to the delicate peritoneal tissues than the bare hand. Strychnine hypodermatically should be given promptly, together with further intravenous saline solution. To the latter may be added hot saline enemas, and the use of the same solution by hypodermoclysis. The author commends also the intravenous injection of a 1-25,000 solution of adrenalin chloride in hourly quantities of 500 c.c. Less success follows the hypodermatic use of the last-named remedy.

**The True Nature of Functional Nervous Diseases.**—W. H. Thomson notes disorder of function even to total cessation, constantly occurs without any derangement of any part of the nervous mechanism. We can seriously affect any motor or sensory function just as we can cerebral action by approprate agents which, once in the circulation, select each one, some particular function which it specifically deranges. The fault here is not primarily in the nervous system at all, but in the blood. It is true that some functional poisons do produce organic changes, owing to their possession of chemical affinities, but they have no necessary connection with primary nervous effects, but such poisons rarely leave any trace evident on post mortem. The body itself is a laboratory in which are produced, many and virulent functional poisons. Some organs are for eliminating these, others for neutralizing them. As to the theory of heredity in the general argument in favor of an organic basis for functional nervous disorders, we must remember that the blood is the most hereditary thing about us, and partakes far more than does any other tissue in transmitting the chief ancestral traits. The old expression that "insanity runs in the blood," may be literally true. One characteristic clinical feature of many nervous disorders is the fact that the attacks are intermittent, while disorders from organic troubles are persistent. The attack is merely an explosion of accumulated toxic material in the blood. Hence, our treatment should be directed toward the discovery and elimination of the special toxic element at the bottom of each individual case Mere symptomatic treatment may alleviate the effect, but does not remove the cause. We must change the diet and bring about intestinal antisepsis. Diseases of this class include especially migraine and epilepsy. In melancholia there may be more than one form of toxemia present. We must examine not only for fecal accumulation, but the high-tension pulse suggests an excess of adrenalin in the blood. Purgation and the administration of aconite will assist in these cases. Finally, the author inquires can a functional disease ever become an organic nervous disease by acquiring a structural basis. He says, in reply that we can conceive it possible that repeated attacks of functional nervous disease, particularly in childhood and youth, may finally impart to some centers an organic basis for either hysteria or epilepsy. But it would be vain to expect that any inspection of convolutions would identify such unfortunately functionating areas.

**Midtarsal Valgus, or Knock Ankle.**—This condition is described by E. H. Bradford, who notes that the deformity occurs at the mediotarsal articulation. The normal motion taking place at this point is effected by a rotation at the hip joint, which twists the whole limb to the outside while the heel and front of the foot are placed firmly on the ground, the astragalus mortised as it is between the two legbones moves with the leg. If the limb is twisted to the inside when the foot is firmly placed on the ground; the weight will fall to the inside of the median line, and vice versa. The midtarsal valgus may result, particularly when the front of the foot is used in walking, while the limb is being moved straight forward and the foot itself is turned outward. A twist in the metatarsus must inevitably result. At first no detriment occurs to the articulation. but if the person is heavy, obliged to stand much, etc., relaxation of the ligament must follow. The characteristic appearance is due to the projection of the internal malleolus. The foot is somewhat distorted in shape. In severe cases the os calcis loses its firm connection with the astragalus, and an excursion under the latter takes place when weight falls on the foot and an astragalocalcaneoid valgus is developed Hallux valgus is often seen in midtarsal valgus. Treatment varies according to the existing condition. We may have (1) normal feet, but with faulty habits of position and gait; (2) flexible, undistorted feet, but with weakened muscles and stretched ligaments; (3) rigid, distorted feet, with structural changes of ligaments, muscles, or bones.

*Medical News, October 7, 1905.*

**Late Hereditary Syphilis.**—R. R. Campbell dwells upon the well-known "triad" of hereditary syphilis (Hutchinson's teeth, interstitial keratitis, and labyrinthine deafness), and also refers to other signs as palatal perforation, atrophic choroidal plagues, and gummata of the skin. Several of the cases reported in literature are summarized, and the author refers to one personal case, that of a girl of sixteen, who began to menstruate at fifteen. At that time she suffered intensely from pains in the legs and nocturnal headaches. On the right foreleg were elevated red spots, varying in size from that of a split pea to almost, if not quite, the size of a twenty-five-cent piece. Within a month the left foreleg presented a similar condition to that on the right leg. When the patient first came under the author's observation she presented typical ulcerating gummata on both legs, without any other evidence of hereditary taint, and an absolutely negative history as to any skin eruption or sickness of any character in the earlier years of her life. The mother of the patient was a subject of ichthyosis, and stated that she had had two miscarriages, occurring without apparent cause; the first at between five and six months, and the second at between six and seven months. On the right hip of the mother, examination revealed a scar, which resembled that following a syphilitic ulceration, although she denied all syphilitic history. The patient's father refused to be examined or interviewed. Under antisyphilitic treatment the girl made a prompt recovery.

**The Ultimate Results after the Bloodless Reposition of the Congenital Hip-joint Dislocation.**—F. Mueller describes the pathological changes occurring in this condition, and the mechanical principles involved in its relief, by the method referred to, and gives two statistical tables of cases operated on by Lorenz during his visit to Chicago in 1902, the subsequent treatment being under his own (Mueller's) direction. Out of 33 cases, anatomical reposition was accomplished in 21. In this series the gait is recorded as having become normal in 15, good in 1, satisfactory in 4, and defective in 1. Motion became full in 16 somewhat stiff, but improving in 2; showed contracture in abduction in 1, while in 2 the right joint was normal, while the left remained somewhat rigid. Out of 12 cases in which a subspinal position was obtained, the joint was good and motion full in all. Favorable anatomical conditions, that is, a general state of the joint, which makes it resemble a normal joint, not taking into account, of course, the present dislocation, unfortunately are formed in scarcely more than 10 per cent. That means that in more than 90 per cent. we have to resort to special artifice in order to improve the lacking stability, and in order to hold the head securely within the socket. Each case must, therefore, be individualized, and the different types must be treated by different measures, with reference to fixation and after-treatment. The author admits that in forty per cent. of the cases, the Lorenz method does not give an anatomical replacement of the head. These are the cases in which the twisting of the femoral neck toward the frontal axis of the condyles is very marked. If the thigh of such a case is held in a normal position the neck is directed directly forward instead of toward the medial line. If we place the thigh, the upper end of which is in such a manner deformed in the so-called primary position of Lorenz, it is evident that the head is not able to emerge through the entrance of the pocket-shaped recessus into the socket, as this entrance is situated in the upper and posterior quadrant of the socket, whereas the neck extends straight from below in an upward direction. The axis of the pocket-shaped recessus of the capsule and the axis of the neck of the femur run in this way in nearly opposite directions. The head therefore, rests at the entrance of the pocket-shaped recessus of the capsule without being encased by it. These conditions can never give anatomical positions with the primary position after Lorenz but only so-called subspinal positions. The head leaves the place in which it has been put and wanders upward finding some resistance in the anterior-superior spine of the ilium underneath which it fixes itself more or less securely. It must be emphasized that a good functional result depends largely on the after-treatment and massage.

**Vesical Fistula.**—H. H Purinton refers to the various operative procedures for the relief of this condition the most common cause of which he finds to be due to injury received in difficult labor. Most of them do not entirely close. The symptoms are described in detail. Boric and carbolic douches should be used until spontaneous healing occurs or an operation is done. The best time to operate is six or eight weeks after delivery. Raw surfaces should be treated with silver nitrate until they heal Encrusted salts should be removed and cicatricial bands excised If there is stenosis of the vaginal orifice, it may be divided with a knife, an incision being made down beside the rectum, which will give the operator room in which to work. This incision may be sutured after the fistula has been repaired. The author then describes his surgical technic, which follows conventional lines. He lays stress upon the importance of a funnel-shaped denudation of the fistula edges as a much larger surface for healing is thereby exposed and a much better result is consequently likely to follow Silkworm gut sutures are preferred. The direction of the line of sutures should be such as to approximate the edges with the least possible strain. The sutures are dusted with iodoform and sealed with collodion. Gauze is packed in the vagina to support the bladder in all movements causing straining, so as to lessen the tension on the stitches.

*American Medicine, October 7, 1905.*

**An Apparently Distinct and Hitherto Undescribed Type of Parasite in Pernicious Malaria.**—H. M. Smith reports the finding in the blood of 119 cases of malaria at the First Reserve Hospital, Manila, P. I., a parasite so peculiar and distinct from any previously described as to render it probable that this form is a distinct type of the parasite of pernicious malaria. The parasites are small hyaline discs of an oval spindle form, non-pigmented and lying in the protoplasm of the red blood corpuscles. They have a very sharply defined outline, are highly refractive, and in the center of each form is a small round dot of hemoglobin. Their short diameters vary from 1-5 to 1-10 the diamter of the red blood corpuscle, their long diameters being about twice as great. On account of their spindle shape, he designates them "spindle forms." They have no ameboid motion, but move by revolving on their long axis and by swinging around on their short axis, using one end as a fixed point. This motion is the most peculiar characteristic of the parasite. They stain with great difficulty, and then only the periphery to a slight extent. No development of any nature has been observed in these parasites, and no forms besides these "spindle forms" were ever discovered in the blood before death, or in the blood and organs after death in the four fatal cases.

**Phlebosclerosis.**—C. F. Martin and J. C. Meakins describe this as a very common condition, which has been recognized as such only by pathologists, some of whom regard it as a process analogous to similar disease in the arteries. These writers, however, find that it exists commonly quite apart from diseased arteries, and that it is extremely common in peripheral veins, especially those of the lower extremities. Their findings and conclusions may be epitomized thus: (1) Peripheral sclerosis is very common, existing in nearly 60 per cent. of patients examined by them in hospitals. (2) It is much more common in young people than is generally supposed, especially in the saphena veins. (3) It is frequently present without any arteriosclerosis (4) Sections show no signs of marked inflammation or degeneration. Proliferation and hypertrophy of intima and media are the chief pathological pictures. (5) The usual causes of arteriosclerosis are absent. (6) The condition is allied to a process of functional hyperplasia rather than to chronic inflammation, and is not associated, as a rule, with injury, though with prolonged strain from movement, posture, and changed blood tension.

**Cervical Rib, with Resulting Gangrene of the Fingers.**—W. Wayne Babcock thinks that the tortuosities or angulations in the subclavian artery, produced by the presence of a cervical rib, are important factors in the circulatory weakness of the hand and arm that occurs in this condition, and points out that the usual forms of occlusion of the subclavian artery are rapidly followed by the development of a collateral circulation, and, if incomplete, are frequently associated with a bruit; conditions not found in association with cervical rib. When apparent widening or aneurysmal dilation of the subclavian occurs, it is distal to the point of compression between the cervical rib and the scalenus anticus muscle and not proximal, as would be anticipated. His patient had developed a marked scoliosis and constantly assumed a position that would tend to relieve the abnormal tortuosity of the artery The patient had noticed a stiffness of the neck at 13, with pain and coldness of the right hand during cold weather. At 20, terminal gangrene, involving the tips of the third, fourth, and fifth fingers, developed, and at 22 the pain and tenderness in the hand became excruciating, especially at night, and this, together with the wasting and almost total disability caused the patient to seek operative relief for supposed frost bite. The skiagraphic evidence was not clear, but the abnormal rib was palpable on very careful examination. Excision of the rib promptly relieved the pain and ischemia, and a faint radical pulse was present ten days after the operation. The chief symptoms of cervical rib are progressive circulatory changes in the hand and arm, unassociated with edemia, but usually associated with some form of paresthesia.

**The After-Treatment of Pulmonary Tuberculosis.**—J. A. Wilder emphasizes the great tendency toward relapse and chronicity of tuberculous ulceration in the lungs as well as in other parts, *e. g.* the skin and bones, and thinks there is a tendency at the present time to take too optimistic a view of its curability. The disease is practically always more or less advanced from the pathological standpoint before it is recognized clinically. Although some patients have such good resistance that they recover in spite of unfavorable surroundings and methods of living, the majority require a continuous life for years rather than months under the most favorable hygienic and meteorologic conditions before there is assurance that their lesions are permanently healed. Placing the patient under proper conditions for a short time often causes the disease to become quiescent, but this is only the first step in the cure of a disease that, on account of the nature and severity of the pathological lesions, is essentially of long duration. In an analysis of 100 cases of pulmonary tuberculosis that have been at least quiescent for from one year to ten years, the average period of quiescence being three years nine months, he finds that at the present time 87 are either quiescent or cured and able to work. Twenty-five of the 100 cases have at some time relapsed. Thirteen of these have relapsed and recovered, eight have relapsed and died, and four are at present chronic invalids. One patient died from cancer of the stomach without relapse of his pulmonary trouble. Of these cases 67 were originally classified as incipient and 33 as moderately advanced or advanced. The period of quiescence before working or returning home varies from no time to 36 months, the average being eight months.

*Journal of the American Medical Association, October 7, 1905.*

**Systemic Blastomycosis.**—D. S. Esendrath and O. S. Ormsby report a case of this disease in a Pole, aged 33, in which the symptoms apparently first appeared in the lungs, simulating tuberculosis, but no tubercle bacilli could be found, and the tuberculin test was negative. While the lungs remained markedly involved, other organs, the kidneys, skin, and subcutaneous tissues also became attacked and the organism of blastomycosis was abundantly demonstrated in the cutaneous lesions, subcutaneous unruptured abscesses (in pure culture), and in the sputum. With these organisms thus derived the local lesions of blastomycosis were experimentally produced. The patient improved decidedly under treatment with iodid of potash, but passing from under observation for a few weeks, suffered a relapse. Further developments will be noted.

**Penetrating Wounds of the Abdomen.**—Randolph Winslow discusses abdominal wounds and gives a lengthy summary of cases treated at the University Hospital, Baltimore. He remarks on the occasional indefiniteness of the symptoms and insists on the importance of early laparotomy, in a well-equipped hospital, if possible. The apparent exception afforded by military experience as to the propriety of prompt operation and in the prognosis of these injuries is noted and accounted for by the special character of the modern military projectile causing a lesser mortality among patients not operated on, and the greater danger of increasing the risks of infection in operation. These conditions do not exist in civil practice, and there the earlier the operation the better. Shock, being usually due to hemorrhage, is not a contraindication; laparotomy should be done at once and the bleeding vessels secured. He insists on the importance of a thorough search in all parts of the intestinal tube, as perforations are liable to be overlooked. Wounds of the stomach and of the solid organs and their special characteristics are noted. Among the cases reported one is of interest on account of the fact that the aorta was pierced by a 32-caliber bullet, making a slit in its anterior surface and an everted counter-opening behind, the bullet then lodging in the third lumbar vertebra. These were the conditions found on autopsy, the patient having lived 122 hours after the injury.

**Water Supply and Sewage Disposal.**—G. W. Fuller discusses the proposed use of copper sulphate for water

purification. Its value as an algicide seems to be well attested, but its effect on drinking water is not yet fully determined and a prudent course at the present time would be to keep water thus treated from use for such purposes. The quantity required for germicidal purposes is much greater than that for destroying algæ, and this makes its use for drinking still less expedient till we have more trustworthy data as to its effects. The use of copper sulphate as a germicide for the effluents of coarse drain sewage filters is mentioned, but the process is an expensive one. The data regarding its use in connection with filtration are not yet sufficient. Altogether a judicious conservatism is advisable as regards copper sulphate. The extent of filtration works in the United States is next noted, and it appears that in the last four years there has been an increase of 70 per cent. in the population supplied with filtered water and a prospect of a still greater increase in the near future. The use of sulphate of iron and lime in treating the St. Louis water supply is mentioned, but it is not considered an altogether satisfactory substitute for filtration. The softening works at Columbus, Ohio, are also commented on as the first instance of a large city using this method in this country. Recent legislative measures in Pennsylvania and New York looking toward the control of water supplies are mentioned with approval. The latter part of the article is devoted to sewage disposal and the conclusion is reached that intermittent sand filters, when available, are the most satisfactory. Coarse-grained filters and sprinkling filters are more or less effective and septic treatment is ordinarily helpful as a preparatory measure. The article concludes with a brief notice of sewage pollution of shellfish and its remedies.

**Maternal Syphilis.**—This subject is discussed by G. S. Whiteside. He thinks the condition is often recognized only by the development of the taint in the infant after birth, and that such cases may be troublesome to the physician. He insists on the importance of being on the outlook for syphilis in the presence of obscure symptoms When it is diagnosed in the pregnant woman mercury should be given promptly and fearlessly to protect the child. After birth the physician should give the syphilitic infant mercury, and with care the child should recover in a few months. After thorough treatment the late forms of hereditary syphilis are rare.

**Lactic Acid in Gonorrhea.**—S. Chandler advocates the use of lactic acid for the treatment of gonorrhea of the cervix as preferable to other methods. He has employed it in thirty-four cases, which are tabulated. His method is as follows: Cleanse the vagina and cervix thoroughly with warm water and cotton soaked in a water solution (four to six ounces) of pyroligneous acid. Expose the cervix by drawing it downward and into view by an ordinary long tenaculum; then take an ordinary hypodermic syringe loaded with pure lactic acid, and inject just beneath the membrane a few drops of the acid Continue this until the whole of the cervix is exposed as the superior and inferior lip is injected. It may be done in one sitting, or in a nervous case, if desired, in two or three sittings. He concludes from his experience with this and other methods that lactic acid cures cervical gonorrhea, has no ill effects and prevents the spread of the disease into the body of the uterus if used sufficiently early. Ordinary douches and painting the cervix give only temporary relief, it is better to destroy the cervical glands, and this should be done as soon as a positive diagnosis is secured. Both the discharge and the cervical membrane should be examined before excluding gonococci, which are the cause of most chronic discharges. This method of injecting the cervical glands with lactic acid, he believes, is the best prophylactic against future disease of the tubes, etc. A too deep injection of the lactic acid may cause an annoying, though not a dangerous, slough, lessening the good result; caution against this, is, therefore, advisable.

**Cephalic Tetanus.**—J. H. Lloyd reports a case of this rather rare variety of tetanus, in which, contrary to the usual rule, the facial paralysis was bilateral As in all other recorded cases of this kind, except one, the original inoculation wound was on the bridge of the nose. He reviews the chief facts of note in cephalic tetanus, and recapitulates briefly the other cases, seven in all, of facial diplegia in head tetanus that he had found in the literature. The peculiar fact that the same infection causes paralysis of one nerve while inducing tetanic spasm in others, is remarked, but cannot be very well explained. Autopsy results, he states, are so far negative. The prognosis of head tetanus is a little better than in the usual type, but it is a grave disease with a very high mortality. Lloyd's patient came within the "chronic" group, the symptoms only appearing on the fourteenth day after the injury, and she made a good recovery. The peculiarities of the case, it being the seventh or eighth thus far reported with diplegia, render it of special interest

*Berliner klinische Wochenschrift, September* 18, 1905.

**The Value of the Hemochromogen Spectrum.**—Dominicis speaks highly of Donogány's homochromogen test for the identification of blood. This consists in the formation of hemochromogen on the addition of pyridin and ammonium sulphide, the spectrum of this substance being easily recognizable. The reaction is successful no matter whether the blood be fluid or dry, soluble or insoluble. By the use of the microspectroscope extremely small quantities of material suffice for the test. If the particle of suspected matter is very minute it is dissolved in a drop of pyridin on a slide, a drop of ammonium sulphide is added and the cover glass placed in position. The preparation is then ready for study, and if positive reveals the purple red color of hemochromogen, the somewhat indistinct crystals of this substance, and the spectrum of hemochromogen. If the blood is in the form of a stain on cloth, a single thread a few millimeters long will yield sufficient material for the test. The hemochromogen test is of universal applicability, and on account of its delicacy is well adapted for routine use in all cases.

**Immunization Against Strychnine.**—Meier is of the opinion that the chemical constitution of strychnine and of tetanus toxin is the same and that both possess one atom complex which gives rise to tetanic convulsions. Furthermore, all toxins or poisons of similar physiological action contain the same or similar atom groups in the molecule. If the body is able to produce an antitoxin against tetanus it should also be able to do the same in the case of strychnine poisoning, in accordance with the assumption that tetanolysin is not an antibody of the toxin as such, but rather the antitoxin of the specific group which gives rise to tetanus. He details experiments on rabbits and guinea pigs which he believes substantiate these views. For example, on injecting into rabbits fatal doses of strychnine, together with a serum or brain substance of animals that had received daily small doses of the drug for some time, no reaction was produced. In another instance some of the brain of an immunized animal was implanted into the peritoneal cavity of a rabbit which three days later was given immune blood serum and a very large dose of strychnine, without causing death.

*Münchener medizinische Wochenschrift, September* 12, 1905.

**Spontaneous Inhibition of Growth in Bacteria Due to Autointoxication.**—Conradi and Kurpjuweit have been able to study the autotoxic bodies developed by bacteria during their growth, and have found that these substances possess powerful inhibitory properties. By adding various amounts of bouillon cultures of different organisms, after varying periods of development, to agar on which fresh cultures of the same and of different organisms were sown, it was discovered that these inhibitory substances are formed from the first hour of bacterial growth, and that their effect increases from hour to hour, reaching its acme after twenty-four hours. Only after six to fourteen days does this inhibitory power subside. Not only is the growth of bacteria of the same species restrained, but also organisms of other species are inhibited. This observation explains the fact that in the ordinary course of laboratory transplantations growth does not begin immediately, but only after the lapse of several hours. It was found that the amount of inhibitory substance formed was directly proportional to the vigor of growth of the culture, and that the substance is intimately connected with the bodies of the bacteria as it cannot be separated from these by filtration or precipitation with alcohol, and is destroyed at the same temperatures as ferments. The authors were able, however, to devise a method of demonstrating the diffusibility of the substances. The inhibitory power of these bodies is much more effective than that of carbolic acid, though they do not appear to be bactericidal. The authors believe that the existence of these substances explains many puzzling phenomena, such as those of symbiosis, antagonism, the overgrowth of certain organisms in mixed cultures, etc., and they propose for them the term "autotoxins."

**Staining Urinary Sediments.**—Wederhake recommends the following methods as being very satisfactory and useful. Neutral red may be used for neutral and acid urines. The urine is centrifuged and the supernatant fluid is poured off down to one c.c. One or two drops of 1 per cent. neutral red solution are added to the fluid, and the sediment is well shaken up. The tube is then filled with water or salt solution, and again centrifuged. The clear red fluid is poured off and the sediment examined. In order to distinguish waxy casts, the following procedure is recommended. Ten drops of concentrated alcoholic solution of methyl violet are added to twenty c.c. of 1 per cent. aqueous neutral red solution. Two or three drops of this mixture are employed inthe above-mentioned manner. Epithelial cells, hyaline and granular casts and leucocytes are

stained red or reddish brown, while waxy casts are deep blue. A method of wider applicability and giving better results without the line urines is as follows: The sediment is shaken up with a drop of tincture of iodine, and then with a drop of a concentrated solution of crocein scarlet, 7B, in 70 per cent. alcohol. The sediment is washed, recentrifuged and examined, or if it is to be preserved is pipetted into glycerin or Farrant's solution. Nuclei will be stained red, the protoplasm of the renal epithelia red, that of the bladder epithelia according to their reaction, (not that of the urine), yellow, yellowish brown or brown. The casts are red, but waxy casts blue. Leucocytes are red. The stain has the advantage of never giving a precipitate, and it yields very instructive pictures.

**Traumatic Gastric Ulcer.**—Fertig describes a case of this unusual lesion. The patient was a man of twenty-eight, who had never suffered from gastric symptoms. He received a kick from a horse in the upper part of the abdomen shortly after a heavy meal. The clinical picture resembled that of internal hemorrhage, or perforation of the intestinal tract, but at the laparotomy performed two and one-half hours after the accident there was no evidence of injury to any internal organ. After the second day, progressively increasing anemia and hematemesis developed, and on the fifth day death resulted. At the autopsy no perforation or peritonitis were found, but on opening the stomach four ulcers were seen along the lesser curvature, one with a large eroded vessel at its bottom. The author considers that injury alone to the gastric mucosa is not sufficient to incite autodigestion, but that the element of infection must be added, as injuries of the mucosa often heal without ulceration. In the present instance he believes that the lesser curvature of the distended stomach was forced against the vertebral column by the traumatism, and several fissures were produced. The stomach was at the height of its activity, so that the healing of the wounds was retarded, and following infection the ulcers developed.

*Münchener medizinische Wochenschrift, September* 19 1005.

**Cytorrhyctes Luis, Siegel.**—Freund says that although almost every week sees the appearance of some communication regarding the presence of spirochetæ in syphilis, the cytorrhyctes luis, which was discovered by Siegel at about the same time, receives very little attention, notwithstanding the fact that there is more evidence in its favor than in that of Schaudinn's organism. The author gives the results of his examination of the blood in seven cases of undoubted, and three of probable syphilis, and states that he reports this small number of cases, not because he attaches great weight to the evidence obtained, but in order to stimulate others to corroborate his work. In all of these cases he was able to find the cytorrhyctes in enormous numbers, his estimate being that 300,000,000 would be present in five liters of blood, a fact which is to be expected, considering the highly infectious nature of the disease. The organisms correspond in all respects to Siegel's descriptions, and the author believes that he can exclude all chances of confusion with blood platelets, hemokonia, portions of disintegrating cells, etc., especially as he was never able to find them in the blood of healthy persons. In three cases under treatment with mercury, the number of flagellates steadily diminished, so that although present in great abundance at first, in one instance they disappeared completely, and in the others could be found only with difficulty. The spirochæta pallida was found in only very few cases, and the author regards it as an organism which, although it is found in syphilitics, has nothing to do with the disease.

**Potassium Permanganate as a Hemostatic.**—Vörner speaks of the various disadvantages attending the application of all the ordinary hemostatics. Even compression is often impracticable in the minor surgery that the practitioner is most frequently called upon to do, because of the undesirably conspicuous dressing it entails. He has found in potassium permanganate an extremely efficient hemostatic which, owing to its antiseptic nature, does not introduce the risk of infection, does not, to any extent, destroy the tissues, and has the further advantage of being very cheap. He uses it either in strong solution, in powder form, or in a paste. He obtains a fine powder by triturating it with one-half its weight of diatomaceous earth, after having first moistened and then dried the mixture. The paste is made with vaseline in the proportion of one part to three. This is most conveniently used in collapsible tubes. If there is bleeding to any extent after the excision of warts, condylomata, small tumors, etc., the bleeding surface is to be wiped dry with a piece of gauze, and the permanganate in one form or the other applied instantly. Usually a single application suffices, but occasionally more are necessary. Any discoloration of the skin about the wound, accidentally produced, is readily concealed by covering it with a piece of zinc plaster. About mucous membranes the paste is preferable, but epistaxis is well controlled with the solution. The patients complain of slight burning after the application of the permanganate.

**A New Plastic Operation, for defects of the Eyelids.**—Elter and Haass speak in very enthusiastic terms of a new method for repairing defects of the lower eyelid, by means of the free transplantation of a portion of the pinna of the ear. Two cases are described. In one, almost the entire lower lid and a portion of the cheek were excised for epithelioma. In order to fill in the gap, a correspondingly shaped piece was cut from the anterior edge of the ear, and its appropriately trimmed raw surface sutured against the defect below the eye. Although the transplanted tissue was found somewhat blue at the first dressings it soon recovered and the cosmetic and functional results described as having been perfect. The injury to the ear healed by primary union and was scarcely noticeable. In another case a bilateral ectropion, due to lupus, was treated on one side by the conventional flap operation, with fairly good results, and on the other side by transplanting a suitable piece of the ear. On this eye the result again was practically perfect. The authors say that this represents the ideal method of repairing defects about the eyelids, because the ear flaps do not contract, are stiffened by their cartilage, and have skin on both sides. They appear to do well in their new situation even though necrosis may seem imminent at first, and the deformity of the ear is always insignificant

*Deutsche medizinische Wochenschrift, September* 21. 1905.

**The Zigzag Incision in Appendicitis.**—Riedel advises the adoption of the invariable rule to operate on appendicitis cases as soon as they are seen without any delay whatever. This tendency is becoming more and more universal in Germany, now that both physicians and the laity are beginning to recognize the wisdom of early operation. The author has endeavored to educate the physicians in Jena and its environs by inviting them to the operations on their patients by giving them the appendices removed for study, and if they are unable to attend the operation by sending them a careful description of the conditions found, illustrated with sketches. As a result of this, during the eighteen months from November, 1903, to May, 1905, 357 appendicitis cases were received. All of these were operated on, 300 of the number during the attack. The 57 interval cases had no mortality; of those taken during the acute stage the mortality was 7 per cent. This the author believes could be reduced to 2.3 per cent. if the cases could be gotten at still earlier. The term early operation, he says, is purely relative, as the nature of the infection varies in each case, so that what might be an early operation in one case would be too late in another. He proposes the employment of the designation "correct operation" to indicate cases in which the surgical intervention occurs while the inflammation is still in its earlier stages. The preferable form of incision is what he calls the zigzag incision. The skin is cut 1½ cm. above Poupart's ligament in a direction parallel to this structure. The external oblique aponeurosis is slit in the direction of its fibers and is held open by retraction sutures so that the internal oblique and anterior sheath of the rectus may be divided, avoiding the small nerve which runs along the outer edge of the rectus. These structures and the transversalis are also retracted by sutures so that a large area of peritoneum lies exposed for the final incision. The wound so made is extremely distensible so that even the whole hand may be inserted, and the pelvic organs, stomach, liver, gall, bladder, etc., may all be investigated through it. There is no danger of hernia, as no muscle fibers are cut across, and what the author considers of especial importance, no nerves are injured, the ilioinguinal and iliohypogastric nerves running close to Poupart's ligament, while the twelfth dorsal nerve is much higher than the line of incision.

---

**Urethrorectal Fistula.**—William M. Beach emphasizes the following facts: 1. Urethrorectal fistula, though comparatively rare, is apt to be overlooked. 2. It is generally of gonorrheal origin, generating prostatic abscess. 3. It may be of traumatic origin by the use of sounds or the operation of lithotomy. 4. The symptoms may point to cystitis, urethritis, and proctitis, in addition to intercommunicability of the urethra and rectum. 5. This is a type of fistula in which suture must be used—a No. 3, 40-day catgut. 6. Care of the wound is of paramount importance. It should never be left to an assistant, for no one can possibly be so familiar with the wound as he who made it. 7. A certain number of cases of urethral origin will heal spontaneously, if recent and the stricture is removed.—*American Medicine.*

# Book Reviews.

Manual of the Diseases of the Eye. For Students and Practitioners. By Charles H. May, M.D., Chief of Clinic and Instructor in Ophthalmology, College of Physicians and Surgeons, Medical Department, Columbia University, New York, 1899-1903; Ophthalmic Surgeon to the City Hospitals, Randall's Island, New York; Consulting Ophthalmologist to the French Hospital and to the Red Cross Hospital, New York; Adjunct Ophthalmic Surgeon to Mt. Sinai Hospital, New York, etc. Fourth Edition, Revised. With 360 original illustrations, including 21 plates, with 60 colored figures. New York: William Wood & Company, 1905.

This excellent little manual has been again revised and improved, and is now in its fourth edition. It is a volume of 391 pages, is a concise, practical, and systematic work, embracing, as the author states, all of the essentials of diseases of the eye. The treatment of such a large subject necessitates brevity and the omission of much that is desired by one who is making a study of any particular disease of the eyes, but the purpose of the work, namely, to supply a practical work for the general practitioner and one to enable the student to obtain a foundation in ophthalmology, is admirably fulfilled. There are no discussions of theories, no references to authors, nothing but the statement of facts and the results of experience condensed. Original illustrations are found wherever they are necessary to elucidate the text. They are abundant but not profuse, nor are they over large. In fact, the volume impresses one with the success of its author in having produced a well-ordered book with as much of real value between its covers as it could well contain.

The colored plates representing external diseases of the eye, which appear for the first time in this edition, are excellent and add much to the value of the volume. Since the work is so well adapted for a very large body of medical men and for all undergraduates in medicine, it cannot fail to become widely distributed.

Zur Kroenleinschen Operation. Von Dr. Josef Helbron, Privatdozent an der Universität und I. Assistent der Universitäts-Augenklinik in Berlin. Mit zwei Tafeln. Berlin: S. Karger, 1905.

In this brochure of 90 pages the author has reviewed the literature concerning the removal of intraorbital retrobulbar tumors with conservation of the eyeball and the operations devised for this purpose without removal of portions of the bony walls of the orbit. He concludes that unnecessary damage is done to the eyeball when methods of this nature are employed. The various operations by which portions of the bony walls of the orbit are removed are then thoroughly reviewed, the author concluding that the Kroenlein operation is the procedure that should be preferred. This operation is carefully described, and brief reports of all recorded cases operated upon by this method are given. The work is very carefully prepared, and the subject is logically considered. It is a very valuable contribution to the subject, and will be read with profit by all who are engaged in the surgery of the eye.

Ophthalmic Neuromyology. A Study of the Normal and Abnormal Actions of the Ocular Muscles from the Brain Side of the Question. By G. C. Savage, M.D., Professor of Ophthalmology in the Medical Department of Vanderbilt University; Author of "New Truths in Ophthalmology" (1893), of "Ophthalmic Myology" (1902); ex-President of the Nashville Academy of Medicine; ex-President of the Tennessee State Medical Association. Thirty-nine full-page plates and twelve illustrative figures. Published by the author, 1905.

The work is one based on a hypothesis which may be said to be original with the author. The writer assumes that there are nine conjugate centers in the cortex of the brain, eight of which have to do with the "versions" of the eyes and one with convergence. These centers control the impulses which cause the necessary contractions of the extrinsic muscles of the eyes. There are twelve "basal" centers which are associated with the cortical centers. These centers have no work to do unless there is some departure from the normal in the action of the extrinsic muscles (heterophoria), in which case their influence is exerted to correct the error. The centers are termed "fusion" centers. The theory is well argued out, but is, of course, without anatomical basis.

Les cardiopathies artérielles et la cure d'Évian, par le Dr. P. Bergougnan, ancien interne en médecine des hôpitaux de Paris. Paris: G. Steinheil, 1905.

In this little book of 150 pages the author discusses arteriosclerosis and its treatment. The diseased condition being regarded as an intoxication, the treatment recommended is eliminative and antitoxic. The author advocates the water cure as practised at Évian; he claims for it that it lowers the arterial tension, and also causes an increase in the output of urea, uric acid, and other urinary solids. Numerous cases are cited in support of this claim.

A Manual of Acute Poisoning—Giving Classification, Varieties, and Individual Substances Usually Met With in Emergency Poisoning, With Special Symptoms, Simple Tests, Chemical Antidotes, Physiologic Antagonists, and Treatment. Together With Methods for Use in First Aid to the Injured. By John W. Wainwright, M.D., Member of the American and New York State Medical Associations, the American Chemical Society, etc. New York: E. R. Pelton, 1905.

The title page expresses in full the scope of this little manual of ninety-six pages. The subject matter is well discussed, and the treatment recommended is correct. The book is small enough to be carried in the pocket, making it particularly well adapted for emergency reference.

A Text-Book of Physiological Chemistry. For Students of Medicine. By John H. Long, M.S., Sc.D., Professor of Chemistry in the Northwestern University Medical School, Chicago. Illustrated. Philadelphia: P. Blakiston's Son & Co., 1905.

This is a brief treatise on physiological chemistry for students, and includes a series of illustrative experiments, printed in small type and interpolated in the text, so that a laboratory course may be carried on with the aid of this volume, along with the theoretical study of the subject. The book does not aim at exhaustiveness, but each of the fundamental themes of physiological chemistry is adequately treated from a beginner's viewpoint. A knowledge of general chemistry and of physiology is presupposed from the reader.

Special features in the work of Dr. Long are the chemical relations of the theories of immunity, which form a field but recently invaded by physiological chemists. Another comparatively new phase of the subject which Dr. Long treats at considerable length is the relation of physical laws (the law of osmosis; the laws of electro-conductivity, and of freezing points) to the physiological chemistry of blood, urine, etc. Here the author's own researches have been incorporated, in a concise manner. Finally, one of the most interesting chapters of the book is that relating to the equilibrium of energy and food ingestion, in which the recent work of Chittenden, Atwater, and others has been reviewed.

Dr. Long's book is noteworthy on account of the thoroughly modern way in which he treats his subject and the clear manner in which he has succeeded in dealing with most complex themes.

Grundris der Semiotik des Harns. Für Praktische Arzte. Von Dr. St. Serkowski, Vorsteher des städtischen chemisch-bakteriologischen Laboratoriums in Lodz. Berlin: S. Karger, 1905.

This unpretentious little pamphlet contains a mass of interesting and practical data bearing upon the significance of the various normal and abnormal constituents of the urine in the diagnosis of disease. The clinical significance of the freezing point, of quantity, specific gravity, and other physical characteristics, and also of the various microscopical features of the urine is given in a very concise manner, but in a clear, didactic style. We recommend the little book to practitioners wishing to be up to date on urine analysis.

The Rheumatic Diseases. By J. Odery Symes, M.D. (Lond.), D.P.H., M.R.C.S., L.R.C.P., Assistant Physician and Bacteriologist, Bristol General Hospital. Practitioner's Handbooks. No. 1. Edited by Harry Roberts. London and New York: John Lane, the Bodley Head, 1905.

This, the first volume of a series called the "Practitioner's Handbooks," is a most attractive and handy book, extremely light in weight, attractively printed, and well illustrated. The author discusses the bacteriology of the various rheumatic conditions so far as is known, and expresses his personal opinion as favoring the view that modified forms of the coccus of acute rheumatism are responsible for certain cases of acute and chronic rheumatoid arthritis. The six sections of the work deal respectively with acute rheumatism, the rheumatism of childhood, muscular and chronic articular rheumatism, acute and chronic rheumatoid arthritis, gonorrheal rheumatism, and scarlatinal rheumatism. The chapter on rheumatoid arthritis is especially interesting, and it is a hopeful sign when the author states that if it be recognized early, and if a definite exciting focus of infection can be determined and removed, there is every prospect of a successful issue. Although not exhaustive, the book contains a very full account of the rheumatic manifestations and their treatment.

# Society Reports.

## AMERICAN PUBLIC HEALTH ASSOCIATION.

*Thirty-third Annual Meeting, Held in Boston, Mass., September 25, 26, 27, 28, and 29, 1905.*

The association convened in the hall of the Y. M. C. A., under the presidency of Dr. F. F. Wesbrook, of Minneapolis, Minn. An address of welcome was delivered by Attorney-General Herbert F. Parker on behalf of the Governor, and one by Dr. Samuel H. Durgin, on behalf of the Mayor.

**Experiments on the Purification of Boston Sewage During the Years 1903-1905.**—Mr. C.-E. A. Winslow and Mr. Earle B. Phelps, Boston, Mass., said the experiments were carried out in cypress tanks, with areas of sixteen to twenty-four square feet, and depths varying from three feet to six feet, placed under cover. It was necessary in any treatment to screen out large floating bodies and to settle out mineral detritus. This process should be limited to a sedimentation of a few minutes. Under such conditions the settled material amounted to some 1,600 pounds per million gallons of sewage, and was of such a character that it might be spread on land without fear of nuisance. A further removal of the suspended organic matter might be effected if desired by treatment in the septic tank. An open tank operated as well as a closed one, and there was no marked advantage in filling the tank with stone. Varying the storage period from twelve to forty-eight hours produced no difference in the effluent, which was measurable by analytical results. All tanks removed nearly two-thirds of the suspended albuminoid nitrogen and produced an effluent fairly free from suspended matter, but darkened by hydrogen sulphide. The tanks, on an average, received fifty pounds of nitrogen as albuminoid ammonia (dissolved and suspended) per million gallons of sewage, of which thirty pounds were discharged in the effluent; fifteen to seventeen pounds were decomposed, and three to five pounds were stored as sludge. In the decomposition of sludge the length of septic period was very important. The amount of organic solids stored, undecomposed, per million gallons of sewage passed was twice as great with a 48-hour period as with a 24-hour period, and four times as great as with a 12-hour period.

Under the conditions of the experiments, crude Boston sewage had been successfully filtered through a two-foot bed of sand, having an effective size of 0.12 mm., at a rate of 0.4 million gallons per acre per day, divided into four doses in the twenty-four hours. With care in construction and operation the sand filter may be efficient at much higher rates than had been generally recognized. Sand effluents were bright, clear and well purified. The depth of the beds could not safely be reduced below two feet. Preliminary septic treatment for twelve and twenty-four hours did not improve the effluents obtained by sand filtration, although it made the care of the surface of the beds somewhat easier. Crude Boston sewage could be treated on single contact beds of fine stone (one-half inch diameter) at a rate of about 1.2 million gallons per acre per day. The effluent, though only partially purified, was generally stable and could be discharged into water without any tendency to create a nuisance. The beds clogged rapidly, and the surface needed much attention. A more practical process was the treatment by the double contact system, in primary beds of two-inch material and secondary beds of half-inch material. Such a combination yielded a fairly well purified and stable effluent at a rate, on the combined double system, of about 0.7 million gallons per acre per day with beds six feet deep. Such a system did not clog seriously. Primary beds slowly decreased in capacity, but a portion of the loss may be made good by resting for a period. Preliminary septic treatment enabled the beds to maintain a higher capacity, but produced an effluent so difficult to purify that their efficiency was interfered with. The most practical method of those which they had studied appeared to be the treatment of crude sewage in double contact beds. The trickling filter remained to be studied. They purpose to continue their work by an investigation of this process during the coming year. For this end a pair of outdoor trickling beds, each 100 square feet in area, had been installed at the station and equipped with a distribution device of an original design.

**Industrial Wastes and Their Sanitary Significance.**—Mr. Marshall O. Leighton, Washington, D. C., read a paper on this subject. Although the study of trades wastes had for many years occupied a prominent place in industrial development, the efforts had been directed toward the economical recovery of valuable ingredients rather than the treatment of objectionable polluting materials. So successfully had this work been conducted that there were some industries in which the by-products had become more important from a financial point of view than the original product. The investigations which had been thus successful had usually terminated when the prime object of the work had been accomplished, and not infrequently the by-product wastes were as objectionable as the original wastes. At all events, if the result had been of benefit to streams and decreased dangerous pollution, it had often been a matter of chance rather than intention. Among sanitary investigators the disposal of trades wastes had occupied in this country a position secondary to that of sewage disposal. There had been a few investigations, such as the classic work of Kinnicutt and Eddy upon acid iron wastes, the investigations of the Massachusetts State Board of Health, and the U. S. Geological Survey; but the fact remained that when a body of sanitarians entered into a consideration of polluting wastes it was accepted as a matter of course that city sewage was the subject for discussion. Yet the problems afforded by trades wastes were often extremely complex, and the study thereof should not be ignored. He classified such wastes as follows: "1. Those which are putrescible or which induce putrescibility. 2. Those which inhibit the reduction or oxidation of putrescible substances or prevent the working of those natural processes by which organic matter is changed to inorganic. 3. Those which appear to be indifferent to chemical changes, but which silt up streams and produce obstructions." While it was true that probably no industrial waste contained the germs of any disease, the subject was nevertheless of prime concern to a public health association. Unstable organic wastes produced a condition of putrescibility in streams. While this might not, of itself, be a menace to health, it was certainly included among those reprehensible features common to modern civilization, which had been turned over to the sanitarian for treatment. It might also be claimed that as a large proportion of this organic matter was nitrogenous, it provided food for bacteria, and thereby extended their baneful influence beyond that at which they would normally remain virulent. Such wastes, too, when discharged in large quantities, increased the burden of water filtration systems, and in some cases rendered them inefficient. In other words, these highly organic wastes were detrimental to rivers from practically all sanitary and economic standpoints.

**The Pollution of Shellfish.**—Dr. George A. Soper said that the fact that typhoid fever might be caused by eating oysters and other shellfish which had been grown or immersed in sewage-polluted water, although well established, was not known as generally as the importance of the subject warranted. The shellfish industries on the American coast were enormous in extent and value. In some places grave sanitary evils occurred. With little exception, there was no sanitary supervision over any part of the business for collecting, handling, and selling the shellfish. Extensive reforms should be initiated if the public was to be protected against the transmission of typhoid and other enteric diseases which were now disseminated in this way, and the interests of the fishermen and others engaged in the shellfish industry were not to

be unnecessarily jeopardized. The nature of these reforms was not a matter of question so much as the method of bringing them about. The remedy proposed was a careful study of the conditions and a wide publication of the principles upon which the corrective measures must be based and applied.

**Sanitary Analysis vs. Sanitary Inspection.**—Mr. R. B. Dole, U. S. Geological Survey, Washington, D. C., said the object of the paper was to draw more general attention to the value of sanitary survey in regions where the potability of water was in question. The writer endeavored to show that detailed local information generally determined the potability of water better than the data afforded by present analytical methods; that therefore boards of health should discontinue the examination of samples of water except those collected in their own study of specific water problems; that funds for water investigation might profitably be expended in the collection of data regarding the natural conditions and industrial and municipal developments which aided in the consideration of water-supply problems. Analytical results and other illustrative material were quoted from a recent investigation of surface waters in Minnesota, conducted jointly by the U. S. Geological Survey and the Minnesota State Board of Health.

**Copper Sulphate in Public Water Supplies.**—Mr. H. W. Clark, Boston, dealt with some aspects of the use of copper sulphate in public water supplies. Experiments to test the bactericidal action of copper were made at the Lawrence Experiment Station. Comparing the action of other metals with copper, he found that the bacteria increased more and decreased slower when in contact with copper than when in contact with tin, lead, zinc, iron, or aluminum. The effectiveness of the metals in destroying bacillus coli appeared to be zinc, iron, copper, tin, aluminum, and lead, in the order named, with tin and aluminum ranking copper in one experiment.

**President's Address.**—Dr. F. F. Wesbrook, Minneapolis, Minn., in this address, said that in America two causes were operative in rendering it difficult to protect the health of the public, one of which was the lack of real knowledge on the part of the public in regard to the scientific truths which underlay the conservation of its chiefest asset, namely, its health, and the other was a tendency in the preservation of individual freedom to lose sight of our obligations to respect the rights and privileges of others who may be less assertive. The speaker discussed a number of things in his address, which was replete with excellent suggestions looking toward the expansion and betterment of the association. The older method of securing experience by experimentation on the public should be superseded by requiring preliminary special training at universities and by boards of health, so that while retaining for the good of the public the service of those already trained and competent, they might be reinforced and, when necessary, succeeded by those who had received such special training. Knowledge of the clinical manifestations of disease was important, but often much more than clinical experience and ability was essential. While in scarlet fever, smallpox, and certain of the infectious diseases it was nearly always possible to diagnosticate the condition present, and by so doing protect others from infection, there were a number of diseases in which clinical observation alone proved utterly insufficient. As illustrating this, he mentioned diphtheria. The policy of the association should be to anticipate demands for special work and special information along the lines which were closely applicable to public health, and care must be taken that with so many societies the members do not lose interest because they had failed to provide a place and a stimulus for workers in all lines which directly affected the work of the association.

**Experiments on the Storage of Typhoid-Infected Water in Copper Canteens.**—Mr. Earle B. Phelps, Boston, Mass. in a paper on this subject, said that in practically all the experiments a number of typhoid organisms lived through the twenty-four hours. Studies on the progressive killing of the organisms showed it to be rapid at first, decreasing rapidly toward the end of the period. The indications were that the surviving organisms were hardy, and would not be entirely killed by a much longer exposure. The efficiency of the canteen fell off rapidly when in continuous use, even with a comparatively soft water. The value of the canteen in actual practice would, therefore, be conditioned upon its being frequently cleaned, preferably with oxalic acid, a practice which would doubtless be neglected in actual field or camp service. The value of the canteen as a disinfecting agent was seriously affected by clay in the water, and was practically destroyed by the use of waters high in alkaline carbonates.

## THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting September* 25, 1905.

The President, Dr. Henry S. Stearns, in the Chair.

**The Relation of Incontinence of Urine to Neurasthenic Symptoms, and Its Treatment by the Isolated Induction Shock.**—Dr. A. D Rockwell read this paper. He stated that incontinence of urine, while mostly a symptom of early age, was not infrequently observed in persons of larger growth. In various forms and degrees it was occasionally associated with that form of neurasthenia where general constitutional symptoms predominated, and sometimes where the manifestations were distinctly and almost entirely local. To relieve a persistent local manifestation was often paramount not only to the relief of many a constitutional derangement, but to other local symptoms as well. The treatment of incontinence of urine, whether by internal medication, by topical applications, or by the various physical methods, external and internal, had yielded, as a rule, results quite unsatisfactory. Electricity in the past had been no exception to that rule. It had been used for the most part as a tonic to the nervous system as a whole, or locally in the form of the galvanic or the rapidly interrupted faradic current. The difficulty had been that in the treatment of incontinence by electricity, we had not sufficiently considered its etiology and pathology. Those cases that were due to an acquired or an organic lesion of the nervous system were generally beyond the reach of any treatment. Fortunately such cases were rare, the majority being known under the name of essentially nocturnal incontinence, due to some dynamic alteration that in our ignorance we called functional. Demonstration had shown the existence of muscular atony, with failure of the external sphincter to functionate properly. This atony was believed to be due to incomplete development of the perineal striated muscles and the external sphincter of the urethra, which thus failed not only in their obedience to the will, but in their response to reflex influences. Such a measure of success as formerly attended Dr. Rockwell's efforts in overcoming this weakness—and it was far from constant or satisfactory—was through the use of the galvanic rather than the faradic current. Within the past few years, however, he had substituted for the rapid vibrations of the high tension coil formerly used, currents of slow intermission, and with distinctly better results. Not every case of incontinence was curable by the isolated induction shock, or indeed by any other method. The principle underlying any form of treatment looking to the amelioration of this annoying symptom of incontinence was to increase the tone of the muscles controlling the act of micturition. We unquestionably failed to accomplish that end by the use of the rapid intermittences of the ordinary faradic apparatus. By that form of application we induced a condition of physiological tetanus, which in the writer's experience had sometimes been followed by an increase rather than a decrease in the severity of the

symptoms. A slow interruption, say one or two per second, had a far different effect. Between each contraction, the muscular fibers had a distinct period of rest, with the result that their power of vigorous voluntary contraction and relaxation was strengthened, and not weakened. In very young children, the treatment was preferably and quite necessarily external, although there was no question but that the best results were obtained by the introduction, when possible, of an olive-shaped electrode connected with the negative pole, until it reached the sphincter muscle. The indifferent electrode, consisting of some flexible metal, covered with sponge or other suitable material, was applied to the abdomen, or, if the muscular contractions following the interruption of the current were objectionable, this electrode might be applied over the sacral region. The technique was simple, but not so simple as to be free from mistakes in its practical application. It was not the slowly interrupted faradic current that was called for, but the isolated induction shock. During the past five years, Dr. Rockwell said, fifteen cases of incontinence had come under his observation, all of which had been treated by the method described. Of those cases, seven had completely recovered, and without relapse; four were greatly benefited, but had suffered various relapses and could not be classed as perfect recoveries, while four had disappeared from observation before giving the treatment a fair trial.

Dr. Margaret A. Cleaves said she wished to emphasize the importance of differentiating between the physiological action of an isolated induction shock and the fast interruptions of an induction coil. The latter method, which was the one commonly used, regardless of the pathology of the condition under discussion, produced a tetanoid muscular action, which exhausted and fatigued the muscle, whereas the slow interruption or the isolated shock promoted physiological contraction. In the class of cases to which Dr. Rockwell had called attention it was of great importance to promote the general nutritional condition; in doing that the incontinence would often disappear, although many cases required this special treatment. Dr. Cleaves said she never used the continuous or galvanic current in incontinence unless is was due to cystitis, when she utilized the action of the currents upon oxidizable metals at the anode. In those cases of enuresis where the condition had lasted from infancy to adult life she had found the static spark of very great value.

**The Vapor Method of Anesthesia.**—Dr. J. T. Gwathmey read a paper with this title (see page 609).

Dr. Franz J. A. Torek said he could corroborate, from personal experience and observation, the statement made by Dr. Gwathmey that the combination of oxygen with other anesthetics, mainly chloroform, would considerably increase their safety. By such a combination, the interference with the respiration and circulation was certainly reduced to a minimum, and in many instances there seemed to be no interference with those functions whatsoever. Even in the hands of an inexperienced anesthetist, such a combination was comparatively safe, and the apparatus demonstrated by Dr. Gwathmey rendered it particularly so. It furthermore did away entirely with the occasional burning of the face by chloroform, which happened often in the hands of very good anesthetists; with the vapor method such an accident was impossible.

Dr. John A. Bodine expressed the opinion that general anesthesia was resorted to entirely too frequently in this city and throughout the United States, and that at least from 25 to 35 per cent. of the operations that were now done under a general anesthetic could be done equally as well and even better under a local anesthetic. This still left from 65 to 75 per cent. of operations in which general narcosis was desirable, and the speaker said he could subscribe to the value of the vapor method of anesthesia. In spite of every precaution, however, death from chloroform was not an infrequent occurrence, and it almost invariably took place during the preliminary stage of the narcosis. In death from any form of general narcosis, one important factor was usually disregarded, namely, fear. The higher the intelligence of the patient, the greater was his fear of this sleep produced by an anæsthetic, and this overwhelming fright, added to the toxemia of the anesthetic, was perhaps the predominating factor in causing death. In the great majority of these cases death occurred in the early stage of the narcosis, when the mental control of the patient was almost in abeyance, but before we would expect to observe any toxic effects from the anesthetic. In a case of death from chloroform narcosis that came under the speaker's observation early in the summer, the patient, a robust, plethoric man, who had received a careful preliminary examination as to his physical condition, died after he had taken less than a dozen whiffs of the anesthetic. It was a well-known fact that fright alone could cause death, and there was good reason to believe that it was the most important factor in the deaths that had been recorded during the preliminary stages of chloroform or ether anesthesia. That chloroform narcosis had never proven fatal to a woman in labor he thought was due to the fact that patients in that condition had no fear of the drug.

Dr. E. W. Lee said that from personal observation and experience he could commend the vapor method of anesthesia demonstrated by Dr. Gwathmey as equal, if not superior, to the forms of administration generally employed. In abdominal work it did away with the muscular contraction of the abdominal wall that so often interfered with the work of the surgeon in that cavity, and in operations about the nose it was much superior to the ordinary methods. He had never seen vomiting follow this form of anesthesia. The speaker said he agreed with Dr. Bodine that the laity, as a general thing, dreaded the anesthetic more than the operation itself, and if they could be assured of the fact that they would be under the care of an expert anesthetist, and that his method of giving the drug was a safe one, it would go far toward eliminating their fears.

**Diagnosis and Indications for Treatment in Surgical Diseases of the Stomach and Duodenum.**—Dr. A. A. Berg read this paper, in which he limited himself to benign conditions. In regard to the diagnosis of benign diseases of the stomach, the main difficulty had been encountered in those uncomplicated cases of gastric ulcer that had given, as the only indication of their presence, a most annoying and distressing pain in the epigastric and right hypochondriac regions. The pain commenced insidiously and grew gradually worse, was not influenced by taking food, and did not come on in attacks. Very slight subconjunctival icterus was present or had been noticed by some of the patients. Repeated and carefully made analyses of the gastric contents in those cases did not throw any light upon the diagnosis. In most instances the gastric juice was normal; occasionally it was subacid, and only rarely was it superacid. A diligent and systematic employment of the *x*-ray, cystoscope, and ureteral catheter, with analyses of the separated urines excluded affections of the kidney as the cause of the patient's complaint, but only by exploratory laparotomy was it possible in some cases to decide between affections of the gall-bladder, vermiform appendix, stomach, and duodenum. Before proceeding to operation in these cases of gastric ulcer, the patients were invariably referred to the internist for dietary and local treatment. Only when that proved of no avail was laparotomy resorted to. Pyloric stenosis from the cicatrization of an ulcer had usually been readily diagnosed from the presence of a dilated stomach, and from the evidences of disturbed gastric motility. In five cases of benign gastric affections the indications for operation had been urgent; in the other sixteen the operation had been done at a time of selection, and only after careful deliberation. Of the urgent operations, two were for acute sudden perforation of the ulcer, with extravasation of gastric and duodenal contents into the free peritoneal cavity, and subsequent diffuse purulent peritonitis; two were for repeated profuse hematemeses, and one for acute dilatation of the stomach. The cases of perforating ulcer with

diffuse peritonitis recovered. Of the two cases of gastric ulcer complicated by sudden profuse hemorrhage, one recovered and one died; in both a rapid posterior gastro-enterostomy with Murphy's button was done. In neither case was there any evidence of fresh bleeding from the ulcer after the gastroenterostomy had been established. In making a decision for operation in the face of bleeding from gastric ulcer, the speaker said he had been guided by the rules which were formulated by Mikulicz and Leube, as the result of their observation and study of a very large number of cases. These rules, which had been accepted by most surgeons and internists, were as follows: Operation was indicated, (1) In the presence of acute, profuse, uncontrollable bleeding, which placed the life of the patient in grave jeopardy. (2) In the presence of frequently repeated bleedings, even if they were not very profuse, that undermined the patient's strength and led to a chronic anemia. Operation was not considered advisable when the patient's general condition was bad, the hemoglobin very low (19 or 20 per cent.), and the pulse rate very rapid. In such a case the operative shock, no matter how slight it might be, whether or not it was combined with the added depressing and hemolytic influence of a general anesthetic, was sufficient to cause the death of the patient. It was far better in such cases to trust to internal remedies and complete rest, induced by morphine, to check the bleeding. When, however, the patient's condition was still good, and the hemoglobin count was above 35 to 40 per cent., an immediate operation was strongly advised.

Dr. Morris Manges said the views presented in Dr. Berg's paper were in general accord with those now held on the subject by most medical men, but he was inclined to believe that a discussion five years hence would show a radical change in those views. In many of these cases we had to deal not alone with a gastric ulcer, but with a patient who was either originally neurasthenic or had been rendered so by his condition, and under those circumstances the removal of the ulcer did not necessarily restore the patient's condition. Another unfortunate factor was the formation of adhesions, with the subsequent development of a perigastritis. The possible occurrence of a vicious circle after a gastroenterostomy should also be borne in mind. All these possible remote effects of operative interference for gastric ulcer should not be lost sight of by the physician, who saw more of these cases than the surgeon. The speaker emphasized the importance of early diagnosis, and if an operation was indicated, the surgeon should not be called in too late nor too soon. In perforation, either of the stomach or duodenum, an immediate operation was indicated; the same rule applied here as applied to perforation anywhere in the intestinal tract. In England, where the condition of gastric ulcer was especially common, Saundby asserted he had never seen any indication to operate for hemorrhage, and claimed that if such a patient was not going to get well by medical means, he certainly would not get well by surgical means, while Moynihan stated that the only indication for operative interference was in cases where there were distinct evidences of ulcer from the symptomatology, and where there was a sudden attack of hematemesis, with great loss of blood and syncope. In such cases the bleeding usually came from a large vessel.

Dr E. Palier said that in the cases of pyloric stenosis he had observed after operation, the improvement had been only temporary. Such operations, he thought, failed to relieve the actual cause of the trouble. In regard to gastric ulcer, Dr Palier emphasized the importance of early recognition and treatment of stomach derangements, so as to prevent the occurrence of serious lesions. Ulcers and hemorrhages were not met with in the normal stomach, and the early recognition of the conditions that led up to them would obviate the necessity of an operation in many cases.

Dr. M. I. Knapp continued the discussion, which was then closed by Dr. Berg.

**Nominations.**—The following names were put in nomination for the ensuing year: *President*, Dr. S. J. Meltzer; *First Vice-President*, Dr. Floyd M. Crandall; *Second Vice-President*, Dr. Walter Lester Carr and Dr. W. H. Park; *Secretary*, Dr. John Van Doren Young; *Assistant Secretary*, Dr. J. Milton Mabbott; *Treasurer*, Dr. Charles H. Richardson.

---

## ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES.

*Fourteenth Annual Meeting, Held at Detroit, Mich., September 26, 27, and 28, 1905.*

(Special Report to the Medical Record.)

(*Concluded from page 599.*)

THIRD DAY—THURSDAY SEPTEMBER 28.

**Some Physical Effects of Gun Fire.**—Fleet Surgeon Lloyd Thomas, R.A., Senior Medical Officer H.M.S. *Excellent*, Naval Gunnery School, Portsmouth, England, read this paper. He gave prominence to some points which concerned the naval surgeon and which were incident to modern methods of big-gun firing at sea. In modern battleships the gun was inside a barbette, turret, or casemate, and so housed all around. In other ships the guns were mounted on the upper deck and not so surrounded. He said it was a very moot point in which position the men suffered more from the firing. The "blast" was a form of concussion which had far-reaching consequences upon those who came within its radius of disturbance, and it was only necessary to be on a level with the muzzle and within a given distance to experience its unpleasantness; if in advance of this plane the shock was intensified and caused very painful symptoms. Examples were to be seen in the case of men standing close to any opening in the ship's side in the vicinity of an explosion, when the membrane tympani could be readily ruptured and doors wrenched from their hinges, and iron stanchions bent. In barbettes and turrets the occupant suffered at first a feeling of great shock; in addition to the violent shaking there was a depressed feeling at the pit of the stomach, followed by a tendency to be sick. Briefly, the effect was one first of compression, and secondly one of suction. After speaking of cordite and the products of its explosion, he referred to the "back-flame" which might give rise to appalling accidents, as occurred on the *Missouri*, where some thirty lives were lost by it. The surgical interests attached to the use of the telescope were few and the injuries caused by it *per se* were slight. The causes of any hurt were to be found in the fixity of the instrument to the gun mounting, and not to any actual recoil of the gun itself. A black eye, or perhaps a wound at the eyebrow, were what they were called upon to attend as a rule.

When a sound ear was injured by gun-fire they generally looked for (*a*) a ruptured membrana tympani, or (*b*) a permanent deafness due to repeated injury of the delicate nerve terminals in the internal ear, this being frequently spoken of as "gun-deafness." If the ear be merely plugged with wool and boracic powder the patient being sheltered from further concussion, the wound heals by first intention; but if the injury be neglected serious consequences might develop. Ruptured drum may be considered to be quite common—out of 300 casualties amongst the Japanese at the naval battle of the Yalu in 1894, nineteen such cases were recorded, and during the French maneuvers of 1897 "several" were recorded. Irreparable deafness ("gun-deafness") was a condition the pathology of which was as yet unknown. Both sides were equally affected. It was not uncommon amongst those who directed the trials of sporting guns at the various butts. Most men kept their mouths wide open during firing operations, and, although this equalized the air on the drum, it must tend to intensify

air concussions on the foramen ovale, and therefore increase the agitation of the fluid in the labyrinth.

Up to the present no device had been found which would sufficiently protect the ear from the violent concussions caused by the modern gun. Cotton wool was often of value, and also a doughy substance had been used for plugging the external meatus. The mouth should be kept open. Experiments had shown that if the irregularities of the auricle were filled with wax or oil the intensity of the sound was weakened, and he had advised the use of vaseline, but with doubtful results. Nipple-shaped india-rubber plugs had been used. Neither officers nor crew take kindly to these artificial means, although the practice was more universal now than a few years ago.

Col. Valery Havard, U.S.A., discussed this paper.

**The Army Canteen.**—Gen. J. D. Griffith, U. S. V., introduced the following resolution, which was adopted unanimously:

*Whereas*, The abolition of the army canteen in the opinion of those best acquainted with the army, has resulted in the use of an increased amount of bad liquors, instead of light wines and beer as sold at the canteen by the soldiers, resulting in a marked increase in diseases tending to the demoralization of the soldier;

And *Whereas*, That it is found that the anti-canteen law adds to the number of saloons and brothels contiguous to garrisons, and as the result, the monthly stipends are spent outside altogether;

And *Whereas*, No benefit whatsoever in any line has been the result of the abolition of the canteen,

Be it *Resolved*, That this body in session do earnestly request the Secretary of War to use his every effort for the reestablishment of the canteen, assuring him of our hearty support in every manner.

Capt. Jeritt of Brooklyn said that the only way in his opinion that those resolutions could be carried out was by taking the matter to the woman at the head of the W. C. T. U. and persuading *her* of the truth of their assertions. If this was not done the women would go to Washington and defeat any attempts to enforce the resolution and to re-establish the canteen system.

**Observations in Japan.**—Dr. Anita N. McGee told of her observations in Japan, where she went with ten nurses with the cooperation of the Philadelphia Red Cross Society, who paid part of their expenses, the rest being assumed by the Japanese Government. They were strictly under orders and formed part of the military establishment. After referring to articles of her own that had appeared in the *Century* for April and May, 1905, she stated that the nursing in Japan was based on German standards, and that Germany influenced the Japanese very much, especially in the colleges. Their female nurses were trained by the Red Cross Society. At Tokio many nurses were ready for service at all times, being stationed there in reserve, which accounted for the report going forth that at that place, with only 161 beds there were 185 nurses, 99 of whom were really partly trained. Their stay in Japan was limited to six months. While in Manchuria she was sent to the post of honor, in western Japan, at the base-hospital. There the serious cases were borne on the shoulders of Chinese coolies; the slight cases walked. The transport system in Japan was most admirable, and was effected very quickly. Russian prisoners were treated the same as Japanese soldiers were Dr. McGee gave a large list of statistics regarding the wounded, deaths, diseases, etc. Kitasato had told her that beriberi he believed to be a contagious disease, and that he was looking for the germ. Neither she nor her nurses saw a case of typhoid fever or dysentery, not being allowed to go near such cases.

Col. Valery Havard, U. S. A., called attention to the absence of ambulances at the front in Manchuria. Also that the ratio of sick to wounded among the Japanese was 4 to 3; while among the Russians this was reversed, viz., 3 to 4.

Gen. J. D. Griffith, U. S. V., said he was struck by the small number of cases of typhoid fever; there were but fifty deaths, a magnificent showing when compared to wha occurred at Chickamaugua, where there were nearly 600 deaths from typhoid fever.

Surgeon-General S. Suzuki, I. J. N., thanked Dr. McGee for what she had said, and remarked that all her statements were correct.

Major George H. Halberstadt, Brigade Surgeon, N. G. Pa., discussed the paper.

**The Real Triumph of Japan, or the Conquest of the Silent Foe.**—Major Louis Livingston Seaman, U. S. V. E., before taking up the consideration of his paper, made a reply to Surgeon Stoke's charges (made in the first day's session) upon his mortuary statistics and comparison between the losses by disease in the Japanese Army and the army of the United States during the Spanish-American War and Civil War. He said that if any member of the United States or the English army believed that he had reflected discredit on the department or personnel of the army surgeons of this country, he tendered his most abject apology, and that he would tender his badge of membership in this association if such was deemed to be the purpose of his actions. He said what he did because he recognized the fact that a terrible and unnecessary sacrifice of life from preventable diseases was due, not to the individual members of the medical profession, but to the system under which they worked. At present in the army the medical officer could only make a recommendation to the line officer to be carried out at his pleasure, and until this feature was remedied and the medical officer made responsible to the President, the defect would remain, and there would be no remedy for the present condition. This was a point that he had been trying to make for seven years. He said that the Japanese minister at Tokio had given him figures to show that there were four deaths from bullets to one by disease during the present war, and that the killed numbered 43,892, or 7.32 per cent. of the entire army, and the wounded 145,527, or 24 per cent. The total number dying from sickness was 11,992.

The success of Japan in the recent conflict with Russia was due preeminently to three fundamental causes; first, thorough preparation and organization for war; second, the simple, non-irritating, and easily digested ration of the troops; and, third, the brilliant part played by the members of the medical profession in the application of practical sanitation, the stamping out of preventable diseases in the army, thereby saving its units for the legitimate purposes of war, the smashing of the enemy in the field. It should never be forgotten that in every campaign an army faces two enemies, the armed forces of the opposing foe, and the far greater and silent foe, disease. Of these enemies, the history of warfare showed that the first, or open enemy, killed 20 per cent. of the total mortalities, whilst the silent enemy killed 80 per cent. The greatest conquest of Japan had been in the humanities of war, in the stopping of this needless sacrifice of life by preventable disease, which was done by the medical men of the army. Longmore's tables, based on records of battles for the past 200 years, showed that there had rarely been a conflict in which at least four men had not perished from disease for one from bullets. Later statistics showed no improvement. In the French campaign in Madagascar in 1894, 14,000 men were sent to the front, of whom twenty-nine were killed in action and 7,000 perished from preventable disease. In the Boer war in South Africa, the English losses from disease were simply frightful, greater even than the Civil War record. But the crowning piece of imbecility, he said, was reserved for our late war with Spain, where more than ten were needlessly sacrificed to ignorance and incompetency for every one who died on the firing line or from bullets. This, too, in a short campaign, the actual hostilities of which lasted about six weeks. The actual number of killed and wounded and sick in the Japanese army from February, 1904, to the end of April, 1905, were about as follows: Killed on the field, 43,892 (7.32 per cent.); wounded, 145,527 (24.27 per

cent.), died of wounds, 9,054 (1.51 per cent.); sick, including other wounds, 162,556 (27.11 per cent.); died of sickness and disease, 7,435 (1.24 per cent.); contagious cases, 4,557 (0.76 per cent.) Total of dead, wounded, and sick 383,548 (64.14 per cent.). He called attention to these startling totals: Killed and died from wounds, 52,946; died from all diseases, 11,992, or nearly five deaths from bullets to one from disease, as against the record of centuries of four from disease to one from bullets; or 900 per cent. better than the average in history. There were 30 men out of every 100 who went to war who were never wounded or sick a day during a year and a half's campaign. There were 2,000 more men died of wounds than from preventable diseases. Of a total mortality from all causes of 64,938, there were 40,934 more from casualties than from sickness. This record was unparalleled and unapproached, and it was due to the medical men. He said that this marvelous result was achieved by engaging with the hidden enemy, disease, which killed eighty out of every hundred that fell in war. The element of disease must be eliminated and they always had this point in view when observers went all over the world to study army systems. With the knowledge thus garnered she evolved a system of her own the motto of which might have been "Prevention, not treatment." Upon the declaration of war she was prepared to house, scientifically treat, and care for 25,000 sick and wounded in Japan alone. One and a half years after the commencement of the war, or on July 6, 1905, the twelve great military hospitals at home possessed a normal capacity of 58,263 beds. Every hospital throughout Japan, and every base and field hospital in Manchuria had its bacteriological laboratory. Captain Tanake, aide-de-camp of Marshal Oyama, told the speaker that there had been but twelve courts-martial in the Manchurian Army, the majority being for cruelty to Chinamen. The number of suicides during the entire war was eighty-six, the majority of them being those who were refused permission to accompany the colors to Manchuria on account of some physical defect, and the remainder, because they preferred death to capture by the enemy. There was but one desertion. After relating some experiences showing ignorance on sanitary matters by prominent officers of the regular army, whose knowledge of sanitation was deplorable, type of men most dangerous to the safety of the army and the nation. Dr. Seaman stated that until the line and staff officers of the American Army were taught the necessity of sanitation and the medical officers are given rank and authority to enforce it, our Medical Department must remain a humiliating feature. Its continuance under present conditions was no less than an evidence of national imbecility. He asked if in our great profession, a profession that in one of the bloodiest wars of history had demonstrated its ability to reduce the mortality of death from disease 800 per cent., was it to remain subservient to the defects of this variety of judgment, or was it to be organized upon rational lines and empowered to enforce its mandates?

Major Borden, U. S. A., wished that every member of the Senate and House of Representatives could be present and made to listen to Dr. Seaman's paper, and so have forced upon them facts that had been there given; this no doubt would result in inestimable good. He did not think that the fault lay with the medical department but with the army as a whole, a fact that Dr. Seaman had repeatedly tried to bring out. He hoped that these efforts along the line of reform would meet with success.

Surgeon Stokes, U. S. N., in defense of his position assumed last Tuesday, said that the point he had endeavored to emphasize was that it was not necessary to mislead the general public to attain their ends, and it was not at all necessary to make the public believe that the medical department of the army and navy was rotten. All he wanted was a correction of misstatements.

General J. D. Griffith, Captain Newkirk, M. N. G., Major Staritt, Ill. N. G., Major Kramer, U. S. V., Colonel W. J. R. Rainsford, R. A. M. C., Major Thomas C. Clark, Miss. N. G., and others, discussed the paper.

**Observations in Japan.**—Surgeon W. C. Braisted, U. S. N., read rections of a very lengthy paper which was based upon notes taken by him when making observations, especially on the Japanese battleships. The military organization was largely from the German standard. The army and navy discipline had no parallel. He gave very careful descriptions of the work done on board ship and in the naval hospitals.

Surgeon General S. Suzuki, I. J. N., said that the powder used by them was non-poisonous, but that cordite, used in the English navy, was poisonous.

**Results of Examination of Recruits for the National Guard.**—Major Charles Adams, I. N. G., gave a summary of the experiences of the Illinois National Guard during the years since the Spanish-American War, in which the examiners had adhered as nearly as possible to regular army rules and forms.

**Gunshot Wounds of the Abdomen.**—Assistant Surgeon General George Tully Vaughan, P. H. & M. H. S., gave a review of fourteen cases of abdominal perforation by gunshot, with comments and conclusions.

Surgeon Chung of China thanked the association for the courtesies that had been extended to him and his colleagues from China.

**Officers Elected.**—*President*, Lieutenant-Colonel Albert H. Briggs, N. G. N. Y., of Buffalo, N. Y.; *First Vice-President* Brigadier General Robert M. O'Reilly, U. S. A., Washington, D. C.; *Second Vice-President*, Rear Admiral Presley M. Rixley, U. S. N., Washington, D. C.; *Third Vice-President*, Assistant Surgeon General George Tully Vaughan, P. H. & M. H. S., Washington, D. C.; *Secretary*, Major James Evelyn Pilcher, U. S. V., of Carlisle, Pa.; *Treasurer*, Major Herbert A. Arnold, N. G. Pa., of Ardmore, Pa. Place of next meeting. Buffalo, N. Y., May 28 to June 1, 1906.

## AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

*Eighteenth Annual Meeting, Held in New York City, September 19, 20, and 21, 1905.*

President, Dr. Howard W. Longyear of Detroit.

*(Concluded from page 559.)*

**Primary Bowel Resection Versus Artificial Anus in the Treatment for Strangulated Hernia.**—Dr. John Young Brown, St. Louis, Mo., limited himself to a discussion of the surgery of those neglected cases in which at the time of operation the intestine found in the hernial sac was so damaged that the operator was forced to resort to one of two procedures, namely, the establishment of an artificial anus, or a primary bowel resection. During the last eighteen months he had operated upon seven cases of strangulated hernia; four of these were males, three females. In four the hernia was of the inguinal variety, and in three of the femoral type. In all primary resection was done, followed by a radical operation at the hernial site. Of the seven cases, six recovered and one died. The oldest patient was 70 years, the youngest 20. The duration of strangulation, longest, 57 hours; shortest, nine hours. Amount of gut removed, longest, four feet; shortest or smallest eight inches. Portion of gut involved, small bowel. In each case the condition of the bowel was such as to leave no question concerning the advisability of its removal. In all the resection was done through a supplemental abdominal incision, and the anastomosis was made with the Murphy button. The results obtained he attributed to the careful attention to certain points in the operative technique, a neglect of which had been responsible for the high mortality invariably accompanying the surgical treatment of this condition. The operative technique employed by the author is as follows: "When a patient enters the hospital with a strangulated hernia, no effort is made to reduce it by taxis

or temporizing methods. Preparation is at once made for operation. This consists of the usual shaving and scrubbing, to which is added a careful stomach washing with water as hot as can be borne. This latter procedure is important, as it rids the organ of the filth resulting from the retrograde peristalsis always present in such cases. As soon as the preparations are completed the patient is anesthetized, general anesthesia being preferred. For ordinary hernia work local anesthesia can be used with comparative satisfaction, but where distended bowel has to be dealt with and extensive resection is contemplated, general anesthesia is safer and far more satisfactory. The classical incision is made at the hernial site, and the sac is reached and opened in the usual manner. Before attempting to relieve the constriction, the sac is carefully cleansed with hot saline solution. This prevents the leakage of septic serum from the sac into the peritoneal cavity. The constriction is now relieved. If the gut distends and its viability is beyond question, it is returned and one of the ordinary radical operations for hernia is begun. If, on the contrary, it is deemed advisable to resect, a supplementary abdominal incision is quickly made. By a careful distribution of gauze the bowel can be delivered through this incision with ease and without soiling the peritoneal cavity. The gut being delivered, the operator has full command of the field. In resecting bowel for this condition, there are three important points to be observed: (1) The resection should extend well back into healthy tissue. (2) The distended bowel above the constriction should be drained of its highly septic contents. (3) The work should be done with the greatest possible despatch. By means of the drainage apparatus (exhibited by the author) the work is greatly facilitated. This drain consists of a medium-sized Keith drainage tube, to which is stitched a long rubber hose. The method of its application is as follows: The extent of the resection having been determined, the bowel is clamped on either limit of the section to be removed. The clamp on the proximal end being placed three or four inches above the point of resection, the gut is now stripped of its contents and a second clamp is placed at the point of proposed incision; the bowel is now incised above this clamp and the drainage tube is placed in its lumen, being retained there by a silk ligature passed through the mesentery and around the intestine. The end of the incised bowel is surrounded with gauze to prevent soiling of the field, the clamp above the drain removed, and the bowel allowed to empty itself through the tube into a receptacle under the table, while the operator proceeds with the resection. The mesentry is now quickly ligated, and the damaged segment of gut removed, and half of the Murphy button is now placed in the distal gut. By the time this is accomplished the drain will have served its purpose the clamp is again placed above the drain, and the drain removed. The other half of the button is now inserted, and the anastomosis completed. As the drain works with the operator, much time is saved, and one of the most important steps of the operation is accomplished, namely, the thorough removal of gas and septic bowel contents, without loss of time, and with no soiling of the surrounding tissues. The bowel is now washed off with hot saline and returned. A heavy gauze pad is placed in the median wound to protect the intestines, while the radical operation at the hernial site is completed. This accomplished, the general peritoneal cavity is copiously irrigated with hot normal saline solution, a glass drainage tube is placed in the vesicorectal pouch, the median wound closed with through-and-through sutures. The patient is now returned to bed, and as soon as possible thereafter is placed in the exaggerated Fowler position. The after treatment is simple. Nothing is given by mouth for forty-eight hours. Saline enemas are administered every three hours, to which an ounce of liquid beef peptonoids is added. If the condition of the pulse should indicate, strychnine and hypodermoclysis are resorted to. Morphine is never used if it is possible to do without it. The drainage tube is generally removed at the end of twelve or twenty-four hours."

**A Study of the Etiology of Floating Kidney, with Suggestions Changing the Operative Technique of Nephropexy.**—Dr. Howard W. Longyear, Detroit, Mich., selected this as the topic of his Presidential Address, December 17, 1903, while operating on a young girl of sixteen years of age for appendiceal disease, the author accidentally discovered that the right kidney, which was normally placed, could be easily pulled down and held in a firm position of complete prolapse by making traction on the cecum. This led to further observation on the etiology of displaced, loose, or floating kidney, both on the cadaver and on the living subject, and afterwards, as a result of these observations, to efforts to devise an operation that should have for its object the retention of the kidney in its normal position as well as the anchoring of the ascending colon in such a manner as to remedy the prolapse of the cecum, which usually obtains in these cases, so that it should not exert further traction on the kidney and through it on the duodenum and renal vessels. The object of the address was to record the results, though unfinished, of these observations. The fact that the kidney in question could be pulled down and held firmly in this position by traction on the cecum and ascending colon was an indication that there existed a more firm and positive attachment of this viscus to the kidney than was generally believed. After considering the literature of the subject, the author naturally assumed that the kidney of his patient was pulled down by the adhesion of the peritoneal attachment, or mesentery of the colon, to the fatty capsule of the kidney, and yet the firmness of the attachment was an apparent contraindication. With the object of testing this point, three cases of floating kidney were operated upon. The peritoneal cavity was entered through the usual incision in the loin, the redundant mesentery gathered up, and attached to the incision in the fascia close to the twelfth rib at the upper angle of the wound. In the first case of extreme ptosis, having had Dittel's crises for several years, the ease with which the operation was performed, the amount of slack mesenteric tissue brought out and attached, and the immediate result which it had of entirely replacing the kidney so it could not be pushed down into the abdomen, were very encouraging. In the second and third cases, however, in both of which the displacement was less pronounced, there was practically no mesentery such as was present in the first case, so that the peritoneal fixation seemed to promise less. However, while drawing out the peritoneal attachment of the bowel and making efforts to push the bowel down, away from the kidney, it was noticed in both cases that there was a cord-like structure passing downward from the lower pole of the kidney, which prevented the separation of the kidney and bowel. This was included with the peritoneal tissue and attached with it. Further investigation of the literature failed to enlighten the author as to the presence of any tendinous prolongation from the lower pole of the kidney, so further investigation was made on the cadaver. The whole upper half of the abdominal parieties being incised and turned downward, the cecum, ascending colon, with hepatic flexure and kidney on the right side, and part of the descending colon with splenic flexure and kidney on the left side, were removed, the dissection being made from below upwards and the organs removed together in such a manner as not to interfere with their normal attachments to each other. On turning the specimens over the posterior surface of bowel and kidney on each side showed a similar formation of tendinous attachment to each other. This was found to be formed by the gathering together of fine longitudinal fibers from the fibrous network which forms the framework of the fatty capsule. The tendinous ridge, formed by its attachment to the posterior surface of the ascending colon, could be followed easily between the peritoneal reflections down to the margin of the lower peritoneal attachment of the bowel and close to the junction of the ileum—in fact, near the point of the so-called origin in the female subject of the suspensory ligament of the ovary. A specimen illustrating the presence of this phrenocolic ligament was exhibited. How much of a causal factor is this

embryological remnant in the production of displaced kidney? This ligamentous union of the kidney and bowel the author claimed was the most important factor in the etiology of nephroptosis. An operation which he had found easy of accomplishment was the fixation of this nephrocolic ligament into the upper angle of the wound without severing it from the colon and also fastening the redundant mesentery, if it be present, in the lower angle of the wound. The convergence of the framework of the fatty capsule into this ligament made a structure of sufficient strength to be depended upon to hold the displaced organs, if securely attached to the aponeurotic tissue, preferably where it was thick, near the twelfth rib.

**Intestinal Obstruction.**—Dr. Lewis C. Morris, Birmingham, Ala., said that delay in operating for the relief of ileus was due to one of two things: (1) Assuming that the diagnosis had been made, the adoption of expectant treatment, with the hope that it would relieve the condition, or that it would recover spontaneously; or (2) the delay resulting from a failure to make a positive diagnosis. The author reported six cases of intestinal obstruction, and maintained that if all such cases could be given the benefit of operation the mortality from this condition would be completely revolutionized. The fact that some cases existed for days and were relieved by operation, led, in cases in which there was an element of doubt, sometimes to delay in surgical interference until the chances for recovery were materially lessened. Occasionally a positive differential diagnosis was very difficult, but the conditions from which a differentiation could not be positively made were almost invariably equally as imperative in their demand for surgical intervention as would be the existence of ileus. The author pointed out what those conditions were. Sudden severe abdominal pain, associated with nausea and vomiting, plus constipation, which did not respond within a few hours to cathartics and stimulating enemas constituted a condition in which the indications for operation were positive. The ability to isolate a distended loop of intestine, the presence of shock and stercoraceous vomiting, go to confirm the diagnosis, but the nature of their presence caused undue delay in operating. The more sudden and violent the storm of symptoms initiating the condition, the more imperative the indications for early operation. To reiterate: after the diagnosis of ileus was made, the adoption of treatment other than surgical, with the hope that it might effect a cure, was utterly unjustifiable in the judgment of the author, and that procrastination, based on the hope of spontaneous recovery, was absolutely criminal.

**Diagnosis.**—Dr. John B. Deaver, Philadelphia, Pa., said there was a tendency at present to make diagnoses (or not to make them) by means of a consultation of specialists—hematologists, bacteriologists, skiagraphers, and microscopists—instead of by a minute, painstaking, and complete physical examination together with a careful study of the clinical history of the patient. Too much stress could not be laid upon the latter. Pathognomonic symptoms were one by one disappearing before the advance of medical and surgical science; but some pathologists and bacteriologists were still ready to give their diagnoses, based solely upon their special findings, with the utmost disregard of the physical examination and of the natural history of the disease in question. As to diagnosis by exclusion, the author said it was manifestly impossible to exclude all but one organ or portion of the body, and therefore a diagnosis by exclusion was an illogical and unscientific method of making a diagnosis. It should always be the last resort. The tendency to base a diagnosis solely, or almost entirely, on laboratory findings was widespread, and becoming more constantly prevalent. The reason that this fondness for laboratory diagnosis was so widespread was, he thought, because the students of medicine were taught laboratory methods to an undue extent. The constant cry in all medical colleges at the present day was for funds to build and equip laboratories. The students were forced to spend hours at a time in the laboratories, studying the products of disease, or the causes of disease, while the time formerly alloted to the study of the disease itself was reduced to a minimum or was altogether expunged from the roster. Instead of drilling into the minds of students the eternal principles of surgery, the faculty sent them to the laboratory to the end that they might become adepts in the art of blood counting, or may be rendered capable of distinguishing between consanguineous tribes of microorganisms. In his judgment this was a fatal mistake. While Dr. Deaver earnestly advocated that every young physician returning to his country town should take a good microscope with him, and should examine his patient's blood and urine on every suitable occasion, yet he was thoroughly convinced of the fact that laboratory diagnosis, as it was called, required now, and ever would require, a well equipped laboratory to render it of any service whatever, and until every physician could possess his own laboratory, or could have a position on the staff of a hospital so equipped, it was worse than useless, it was a criminal waste of time, and a menace to their future patients, to endow students with no skill but in such mechanical methods.

**Appendicitis As a Factor in the Diagnosis and Treatment of Abdominal and Pelvic Tumors; Also Complicating Pregnancy.**—Dr. Rufus B. Hall, Cincinnati, O., believed that the diagnosis of appendicitis, when associated with pelvic and abdominal tumors, or in the pregnant woman, had not received the attention on the part of the general profession that the subject deserved. He called attention more forcibly to the early recognition of the cardinal signs of appendicitis in these cases. It was a common supposition on the part of the general profession that when a patient known to have an abdominal or pelvic tumor was taken suddenly ill with pain in the abdomen, that there was something wrong with the tumor and the cardinal signs of appendicitis were ignored or overlooked. The author then discussed the differential diagnosis of appendicitis complicating fibroid tumors of the uterus and ovarian tumors; the differential diagnosis of appendicitis complicating tubal disease; the differential diagnosis of appendicitis associated with pregnancy; the treatment of appendicitis complicating fibroid tumors and ovarian tumors and tubal disease, as well as the treatment of appendicitis associated with pregnancy.

**Cesarean Section.**—Dr. Henry Schwarz, St. Louis, Mo., reported an unusual case of a child-wife who was in labor sixty hours, with repeated attempts at forceps delivery by the family physician. Apparently she was not infected. Instead of a Porro, as was usual in such cases, he did the classical cesarean operation, which was followed by the recovery of the mother. The baby was asphyxiated; membranes and amniotic fluid were yellowish-green. His assistant worked over the baby an hour at artificial respiration before spontaneous breathing was established. Pressure marks on the scalp showed locking of the head between the promontory and symphysis; necrotic tissue dropped out a few days afterwards, and the baby recovered.

**Pregnancy Associated with Diabetes.**—Dr. Magnus A. Tate, Cincinnati, O., mentioned the reports of numerous investigators, calling attention to sugar in the urine of pregnant women. He collected all cases that could be found in literature where pregnancy was complicated by diabetes. He reported an additional case, and presented a study of these tabulated cases as to their frequency, results, mortality, and other similar data.

**Cysts of the Mesentery.**—Dr. Orange G. Pfaff, Indianapolis, Ind., said that these growths were comparatively rare; their diagnosis was difficult, if not impossible. Their pathology was not fully and clearly understood, but most of them, if not all, were of probable embryonal origin. He reported two interesting and instructive cases of mesenteric cysts.

**Abdominal Pregnancy Persisting Beyond the Normal Period of Gestation, with Report of Cases.**—Dr. Charles A. L. Reed, Cincinnati, O., read a paper which was based, first, upon three cases that occurred in his practice as

follows: (1) Extrauterine pregnancy with extraperitoneal development of gestation, operated upon fifteen months after conception by marsupialization, and terminating in recovery. (2) Extrauterine pregnancy with retroperitoneal development of gestation, operated upon by marsupialization eleven months after conception, and ending in recovery. (3) Extrauterine pregnancy with the development of gestation within the anterior abdominal wall, complicated with uterine fibroids, operated upon four years and nine months after conception, ending in recovery. The author next presented résumés of seven cases in the practice of other operators, representing various other forms of development of extrauterine pregnancy. The conclusion reached by Dr. Reed was that the placenta presented the chief factor of danger in operation upon these cases. In instances in which the fetus was already dead, and in which there were no symptoms of sepsis demanding immediate operation, a delay for a few weeks was desirable, as thereby the vascularity of the placenta would be greatly reduced, if not entirely destroyed. One case indicated that it might persist to an embarrassing degree after six weeks. The operation by marsupialization was recommended, as it avoided hemorrhage, facilitated perfect drainage, and placed all conditions under control. The importance of the yeast ferment in eliminating attached fragments of placental detritus was emphasized.

**Observations on the Treatment of Face Presentations.**—Dr. Augustus P. Clarke, Cambridge, Mass., said that typical cases of face presentation were not common. Undoubtedly nearly all cases of such presentation were originally brow positions, but by some irregular uterine contraction and other incidental factors they changed to the character of face presentations. If the occiput was anterior in a face presentation, naturally delivery became impracticable. Schat's method for relief by external manipulation had its advantages as an initial measure. In dolichocephalic cases other methods would be demanded. Podalic version would sometimes be successful. In mentoposterior presentation rotation of the chin should be made toward the symphysis pubis. If the child was not dead, and the case was that of mentoanterior presentation, and impaction was taking place, and the maternal pelvis was not too narrow, forceps might with benefit be used. In a mentoposterior presentation, when the case was seen late and the position of the face could not be conveniently changed, and the child was still alive, symphyseotomy offered the best method of procedure for saving both the mother and the child.

**Myomectomy.**—Dr. Walter P. Manton, Detroit, Mich., contributed a paper in which it was stated that the ruthless sacrifice of the uterus in many cases of single and multiple fibromyomas of that organ was greatly to be deprecated, and the influence of good surgery should be toward the discountenancing of such unnecessary procedure. Myomectomy afforded relief in a large percentage of these cases and had the advantage over hysterectomy in that the uterus was conserved, its tissues put in the way of renewed health, and functional activity restored. Under modern methods, in skilful hands, the dangers from this operation—hemorrhage and sepsis—so greatly feared by the older operators, had been practically removed, and in suitable cases almost any number of tumors, wherever situated, might be enucleated with satisfactory results. In determining on myomectomy as the operation of choice, the age and physical condition of the patient, the arrangement and distribution of the tumors, and the amount of uterine musculature present must be given chief consideration.

**Officers.**—The following officers were elected: *President*, Dr. John Young Brown, St. Louis, Mo.; *First Vice-President*, Dr. James N. West, New York; *Second Vice-President*, Dr. Frank F. Simpson, Pittsburg, Pa.: *Secretary*, Dr. William Warren Potter, Buffalo, N. Y., reelected; *Treasures*, Dr. X. O. Werder Pittsburg, Pa. reelected; *Members of Executive Council*, Drs. Robert T. Morris, New York, and Howard W. Longyear, Detroit, Mich.

## MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

*Fifty-fifth Annual Meeting, Held at Scranton, September 26, 27, and 28, 1905.*

**(Special Report to the Medical Record.)**

(*Continued from page 602.*)

SECOND DAY—WEDNESDAY, SEPTEMBER 27.

**Address on Otology.**—Dr. Michael V. Ball of Warren in this address gave a summary of the accomplishment in the last four years in otology. The electrolytic treatment with bougies was mentioned as an instance of some things which had not proven so beneficial as hoped for. Harris of New York, he said, had found that it was of no value in otosclerosis, that it had some value in a narrowed Eustachian tube and in relieving tinnitus, that it was not without danger, and that in the majority of cases it was not really an electrolytic process. Reference was made to the so-called Baginski treatment for labyrinthine diseases by lumbar puncture. In the radical operation for chronic suppurative otitis the tendency was to become more bold and to make a thorough excision of every particle of diseased bone, using skin grafts to enclose the cavity. The speaker felt that the old method of treatment of a chronic ear suppuration by cleansing with lotions and powders must give way to surgical means. In the matter of the mastoid operation he insisted that the mastoid cells might be thoroughly diseased while many of the classical symptoms were absent. The method of transillumination of the mastoid region through the ear he thought of value.

**The Present Treatment of Squint.**—Dr. Wm. Campbell Posey of Philadelphia said that all children were more or less predisposed to squint, dependent primarily upon vicious optical conditions. The vision in the squinting eye he believed rapidly deteriorated. Treatment he outlined under the following heads: (1) The improvement of the vision in the defective eye; (2) neutralization of the far-sightedness and the lessening of the accommodative effort, and (3) the strengthening of the nervous and muscular mechanism which controlled the movements of the eyes, and the cultivation of the desire for binocular vision. Attempts to improve the vision should be inaugurated at once, since improvement could not be secured in subjects over six years of age. At the age of two or three years glasses should be prescribed, and when the child was older, vision might be still further improved by the use of the amblyoscope, a modified form of stereoscope introduced by an English ophthalmologist. In a certain number of cases he believed the eyes could be made straight only by tenotomy. The amblyoscopic exercises should be continued for a year or more after operation.

Dr. S. D. Risley in opening the discussion of Dr. Posey's paper said that binocular vision was in every one a question of experience, as for example, an infant would reach out for an object held up to it, but its hands would never go directly toward the object desired until it had learned by experience where the object was and how to find it. This he regarded as a species of muscular sense acquired by experience. So in binocular vision the infant had to learn to use both eyes at the same time and to converge upon the object. The fact that one child acquired binocular vision readily and another child obtained it only with the aid of optical appliances he attributed to anatomical anomalies.

Dr. Taylor of Wilkes-Barre disagreed with Dr. Posey that benefit could not be secured for the child after six years of age, and had seen many cases improved by the use of properly fitted glasses after this age.

Dr. Posey in closing said that he did not think the correction of squint could be undertaken at too early an age.

He considered it important to study the character of the deviation and ascertain the exact muscle at fault.

**Herpes Zoster Ophthalmicus.**—Dr. Edward Stieren of Pittsburg said his observation of six cases of the ophthalmic variety of the disease included two showing a wide disparity in the eruptive process and ocular involvement, and these two might be considered classical illustrations of the extremes of herpetic eruption following the course of the fifth nerve. A history of the maximum and of the minimum case was given with photographs of each. The patient suffered an enucleation in the maximum case. In the minimum case there had been the disappearance of a bleb which had been observed upon the limbus, leaving, however, a decided scar and a slight patch of congestion which persisted for several months. In all the cases of this affection Dr. Stieren has been able to trace a history of exposure to cold or dampness after some unusual exertion, with consequent fatigue, in individuals of otherwise sedentary habits.

Dr. Zentmayer of Philadelphia believed it an extremely rare occurrence for herpes zoster to take such a disastrous course as illustrated in the first case. He cited a case complicated by the occurrence of ocular motor palsy and corneal ulcer in which the ulcer healed promptly but in which the palsy was of several years' duration.

Dr. Stieren in closing said he thought the disease seemed to run a self-limited course and that there was a certain amount of immunity given a patient who had had one attack. Rather against the hypothesis that the disease was an acute infectious disease was the fact that seldom, if ever, was more than one case found in a household.

**The Mastoid Operation.**—Dr. Edward Bradford Dench of New York City read this paper. He believed that in 99 per cent. of the cases the disease was secondary to an inflammation of the middle ear. The most characteristic symptom in his opinion was tenderness on firm pressure over the mastoid process. The prognosis in mastoid operations he believed to be excellent. Out of 489 operations by himself there had been but twenty deaths, and in none was death due to the mastoid involvement. The first point in the technique which he insisted upon was absolute asepsis. The operation was described in detail. The second incision, extending horizontally backward from the middle of the curvilinear one, of which much had been said of late, had in his practice been rarely necessary. The possibility of three accidents during operation was mentioned; these were (1) failure on the part of the operator to find the mastoid antrum, (2) injury to the lateral sinus, and (3) injury to the facial nerve. Variations in technique were necessary in young children. In the after-treatment he usually allowed the cavities to fill up by granulation In most of the cases the hearing following operation had been excellent.

**Mastoiditis—Its Importance in General Practice.**—Dr S. MacCuen Smith of Philadelphia in this paper gave a brief outline of the historical aspect of mastoiditis, and then directed attention especially to its relation to general practice A physical sign of the greatest diagnostic importance he said, was the ominous bulging or drooping of the superior and posterior wall of the external auditory canal. The most urgent measure in the treatment of mastoiditis arising from acute tympanic disease he emphasized as early and free incision of the membrana tympani, especially when complicating infectious disease—that is, opening of the drum head during the stage of hyperemia and before the stage of pus-formation has been reached. In the after treatment of myringotomy the canal was dried with a cotton-wrapped probe, and then an impalpable powder was dusted on the walls of the canal. Emphasis was placed upon the word "dusted," as much powder would impede drainage

Dr Taylor of Wilkes-Barre was glad that Dr. Smith had referred to the pernicious idea that a child would outgrow a "running ear," and that it was dangerous to stop a discharge of the ear.

*(To be continued.)*

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 7, 1905:

| | Cases | Deaths |
|---|---|---|
| Measles | 52 | 2 |
| Diphtheria and Croup | 198 | 19 |
| Scarlet Fever | 58 | 1 |
| Smallpox | .... | ..... |
| Chickenpox | ..... | ..... |
| Tuberculosis | 381 | 168 |
| Typhoid Fever | 97 | 14 |
| Cerebrospinal Meningitis | 12 | 14 |
| Typhus Fever | ..... | ..... |
| Yellow Fever | ..... | ..... |
| Cholera | ..... | ..... |
| Totals | 798 | 218 |

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the period from September 23 to 30, 1905:

SMALLPOX—UNITED STATES.

| | | CASES. | DEATHS |

### A PLEA FOR LOCAL ANESTHESIA IN THE RADICAL CURE OF INGUINAL HERNIA, BASED ON A STUDY OF 300 CASES.*

By JOHN A. BODINE, M.D.,

NEW YORK.

PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC.

This communication presents a personal experience of 300 radical operations for the cure of inguinal hernia under local anesthesia. The patients number 284; 16 were double ruptures; 275 males, 9 females. The youngest was 15, the oldest 80. Ten were strangulated. The omentum was amputated in more or less quantity twelve times. The appendix was found with the contents of the sac three times and in each instance was excised. Undescended testicle one time; castration. Hospital detention two weeks; away from work one week additional. The amount of cocaine used in no case exceeded ½ grain. No wound suppurated. No patient died.

It is a general custom to limit the use of local anesthesia to operations of short duration and especially to ailments not justifying in their nature general narcosis. There is incongruity at times in the selection of the anesthetic. Painful, inflamed fingers are amputated under cocaine, possibly on the principle that a minor operation justifies a minor anesthetic, while ether is employed in the suture of a fractured patella. In these instances the anesthetic should be reversed. Furthermore there is a disposition to rest satisfied with reducing the pain within the limit of endurance. In nearly all instances the entire abolition of pain can be accomplished by the proper use of cocaine. The cause of imperfect results probably lies in the fact that the newer methods of using the drug are not widely understood. A common proceeding is to inject into an area a few drops of 4 per cent. solution, wait a few moments for diffusion, cut as long as the patient will stand it, inject more, and so on to completion of operation. This is the old regional method. Schleich's infiltration marks a wonderful step forward. The strength of the solution is reduced to a minimum and, contrary to the idea of diffusion, the solution is packed so densely in the tissues as to produce acute local anemia, effectually retaining the drug at that spot.

Corning's discovery that cocainization of a sensory nerve trunk abolished pain-sensation throughout its area of distribution made it possible to extend the use of local anesthesia from minor operations into the field of major surgery. It is this fact of "nerve-blocking" that makes possible a painless dissection for the radical cure of inguinal hernia.

The anatomy of the inguinal region is so constructed, in accessibility, regional restriction, paucity of blood-vessels, and above all in sensory nerve supply, as to make the operation in question the most favorable in general surgery for local anesthesia. We are indebted to Cushing of Baltimore for prominently bringing forward the propriety of local anesthesia in cases of rupture when a contraindication to cerebral narcosis exists.

Consider for a moment the regional restriction in the field of operation and the superficial position of the operative area. Neither nerve trunk nor sizable blood-vessel is encountered in the skin or subcutaneous fascia. Beneath the aponeurosis of the external oblique lie the three nerve trunks that preside over sensation in the entire field of work. The inguinal branch of the ilioinguinal, hypogastric division of iliohypogastric and genital branch of the genitocrural are the three nerve trunks in question. If all are found and cocainized the operation afterwards is totally devoid of pain. Their identification is not difficult. The first two named lie between the two oblique muscles directly under the incision. The genitocrural is usually among the structures of the cord. The nerves are named in the order of their pain-bearing importance and in the order of constancy in anatomical position.

All three are derived from the first and second lumbar trunks and participate feebly in forming the lumbar plexus prior to entrance upon the field of this operation. Intercommunicating branches pass from one to the other throughout their course, which explains the comparative freedom from pain after cocainization of the ilioinguinal though the other two are not found. The largest, most constant, and easiest found is the ilioinguinal. It runs from the iliac crest inwards, resting upon the surface of the internal oblique and is always to be found running a course parallel to the long axis of the hernial protrusion, sometimes as far outwards as the shelving process of Poupart's ligament. If it is large, the iliohypogastric is small and correspondingly inconsequent, and but little time should be spent in search of the latter. They invariably bear inverse proportion in their size. The iliohypogastric may be absent and, as stated, is less faithful in position. In fact it may be ignored if the margin of the internal ring is properly infiltrated. Generally it lies upon the internal oblique an inch or more above the arching fibers of the internal ring. The genitocrural is also inconstant in situation and is frequently not identified during the operation. It emerges from the internal ring along with the cord and consequently behind the neck of the hernial sac. It possesses an unimportant pain-bearing consequence.

An apology is due for this imperfect anatomy, but together with Cushing's drawing of these nerves the ilioinguinal can be found always, the iliohypogastric frequently and the genitocrural at times. This uncertainty of position is not discouraging, as the all-important ilioinguinal can be found and the operation completed without pain by infiltrating areas known to be sensitive. To substantiate the claim that local anesthesia is an improvement on general narcosis in this operation it should withstand a comparative criticism of safety to patient,

* Read before the New York County Medical Association.

thoroughness of operative detail and freedom from pain.

*Safety to Patient.*—The mortality, in the hands of a clean surgeon, of operation for inguinal hernia as at present practised is practically the mortality of the anesthetic. General narcosis has a danger, small, it is true, but sufficient to be considered by the surgeon. To the laity it is the greatest deterrent factor in the operation.

It is an obvious proposition that a solution of cocaine injected intermittently into the circulation, amounting in all to ½ grain and occupying one hour in the introduction, is less dangerous than ether or chloroform carried to full surgical narcosis for the same period of time. In strangulated hernia with profound shock and toxemia this method finds an imperative application. General anesthesia is often a load too heavy to bear.

Patient of Dr. Barker, Woodside, L. I., admitted to St. John's hospital March 16, 1905. Hernia strangulated for eight hours. Profound shock with usual weak, thready pulse. Operation under local cocaine anesthesia. After relieving constriction, the gut was found to be of doubtful vitality. Hot saline towels were applied to the loop for possibly thirty minutes, when the color was restored. The radical operation was then completed and the patient returned to bed. Instead of increased shock from ether, the pulse and general condition of the patient improved during the operation. There was no complaint of pain.

Not infrequently the vitality of a strangulated coil of gut can be determined if hot saline towels are applied long enough. With local anesthesia these may be applied for an hour or more. General narcosis for this length of time, added to the existing shock, may take away the chance of recovery. The alternative is to resect or return the doubtful loop. Fatal consequences from a wrong decision is a possibility.

It is quite probable that fewer wounds will suppurate under local anesthesia. The very nature of the anesthetic compels gentle handling of the tissues. This lack of bruising leaves the wound in best possible condition to resist infection. Primary healing is essential to cure. In none of my cases was there suppuration. Textbooks and monographs are strangely silent on the importance of respecting the structural integrity of these nerves, yet they preside over the strength and nutrition of the structures concerned in preventing recurrence. Division of the genitocrural produces atrophy and relaxation of the cremaster muscle. Division of the ilioinguinal and iliohypogastric will no doubt produce like results in the conjoined muscle and tendon. When authoritative teaching ignores their importance it is quite certain they are often sacrificed. Under local anesthesia these nerves are left intact and the cocaine affects them functionally only for a time.

Danger to the line of deep sutures from nausea and vomiting is obviated. This is an important point indeed. It is conceivable the powerful abdominal muscles might tear out some or all of the deep sutures during the violent vomiting before full consciousness returns.

Much of the prevalent idea of the toxicity of cocaine is exaggerated. It comes from the alarming symptoms reported during the early days of its improper use in surgery.

Strong solutions were permitted to enter the circulation before incision relieved the tension. Many of the idiosyncratic effects reported were psychical phenomena—the result of a lively imagination regarding the coming operation. This psychical shock is occasionally noted now, but is properly placed. The symptoms are in part similar to those of cocaine poisoning—pallor, sighing, rapid pulse, and facial perspiration. Recumbency and aromatic spirit of ammonia bring about rapid restoration. Attention to the concentrated solutions applied daily to the vascular nasal and pharyngeal membranes gives a better understanding of the relative toxicity of this drug. The maximum safe dose in all cases under all circumstances has not been determined. Analogy proves there is one, as in the case of strychnine, hydrocyanic acid, and other poisons. None will gainsay the statement that intermittent injections throughout the period of an hour, amounting in all to ½ grain, are well within the limits of absolute safety. We have come to regard morphine as not only the antidote to cocaine in its graver manifestations but, by its calmative effect upon the nervous organization, a trustworthy preventive of the psychical phenomena just mentioned. It is our custom to administer hypodermically morphine ¼ grain prior to the operation. In none of our cases was even the exhilarating effect of cocaine observed.

*Thoroughness.*—As no temptation exists to save the patient pain, no detail of the operation essential to cure is omitted. The work proceeds with the same deliberation and thoroughness as under ether. The patient remains quiet, placid, and contented. We have practised, as the case demanded, all the variations of the simple form of operation. Bloodgood's transfer from the rectus muscle, to supply a deficient conjoined tendon, once. Sliding the sheath of the rectus muscle into the same situation, as suggested by Halsted, once. The stitch above the internal ring, as recommended by Coley, in nearly all cases. Excision of existing varicocele twelve times. Amputation of adherent omentum causes no additional pain.

In one instance a mass of lumpy omentum weighing sixteen ounces was ligated in sections and amputated without additional cocaine. There was shock and some nausea, but no pain. Cutting and tying the omental blood-vessels seems to give no pain, which is not true of similar structures elsewhere. Traction on the omentum nauseates the patient.

Undescended testicle complicating rupture was encountered once. Operation August, 1904, at Houston, Texas—patient of Dr. Sampson. Young man, twenty-one years, with omental rupture on right side. An undescended and undeveloped testicle lying high in the canal. The cord was too short to permit anchorage in the scrotum, and as the functional value of the organ was in question the patient demanded its removal. The cord was included in the transfixion-ligature at the neck of the sac and the testicle removed. Some pain at moment of tightening ligature but not enough to cause movement of patient's body.

The appendix was found three times as part contents of the hernial sac. In each instance it was amputated and stump inverted without additional cocaine and without pain. Many times the gut has been withdrawn gently, handled freely, and returned to the cavity without pain. Forcible traction on the mesentery will, however, cause both pain nausea. As the visceral handling in the average case of rupture is both simple in character and short in duration it can be thoroughly accomplished.

No case of strangulation has yet demanded resection. On this point our experience does not justify an opinion. The size of the protrusion does not constitute a limitation to the method. Patient of Dr. E. N. Shaw operated upon August, 1904, at Cameron, Texas. The tumor, size of adult head, was carried in a bag, a truss being ineffectual. The operation under cocaine was as free from pain as

any in the list. Neither size of tumor nor contents of sac form a limit to this method. Very fat patients require too much of the solution to give freedom from pain during incision through the adipose layer and the wide retraction necessary to expose the field. Children too young to understand and appreciate are obviously unsuited for local anesthesia.

*Pain.*—The amount and degree of pain suffered by patients are purely relative, and a difficult matter to determine. They differ widely—great pain to one is slight pain to another. Patients have not been selected with a view to their pain-bearing capacity. Different types are here represented, from the stolid and phlegmatic to the neurotic and imaginative. In not a single instance was there complaining, restlessness, nor movement of hand nor foot during the operation. That the method is passed along from patient to patient in the ward and requested instead of ether is good negative evidence on this point.

As types of the intelligent patient, take the following two: Clergyman operated upon at St. Joseph's Infirmary, Houston, Texas, in presence of visiting physicians. Patient requested by physicians to give opinion at close of operation answered, "There was a rather disagreeable momentary expectation of pain that did not materialize." A physician operated upon before the Tri-State Medical Association at Greensboro, N. C., March 1, 1905, summed up his experience as "wholly insignificant in pain." At the New York Polyclinic, February, 1905, an Italian laborer who could not speak English refused operation unless "put to sleep." Under persuasion he permitted trial of this method with promise of ether "if it hurt." The operation was completed without evidence of pain. Finally, an old negro man, eighty years, incapable of enjoying otherwise good health on account of large incarcerated hernia. Tumor measured twenty inches in circumference, and when unsupported reached half way to his knee. Operation at Fort Worth, Texas, August, 1904, Drs. Thompson and Saunders assisting. The large mass of intestine was freely handled and returned to the cavity without any expression of pain from the patient. The clergyman, doctor, the frightened Italian, and the negro, would seem well to represent types of intelligence, imagination, and fear. We can safely say the pain endured is not as disagreeable as the nausea following ether.

*The Cocaine Solution.*—Two-thirds of a grain of cocaine is a safe dose. In no case have we exceeded ½ grain. It is not grudgingly doled out to the patient but freely used upon the slightest complaint of pain. One grain is dissolved in one ounce of sterile salt solution, making a strength practically 1-5 of 1 per cent. This stock solution is used for skin infiltration and cocainizing the nerve trunks. For all subdermic infiltration a solution half this strength is used. This second dilution is made in the syringe by drawing it half full of the stock solution and half full of a physiological solution of salt. We have experimented with solutions stronger and find them unnecessary, while weaker solutions do not produce perfect anesthesia. When properly infiltrated a solution of this strength will completely anesthetize the skin for one hour and a half. It should be made fresh, as cocaine solution rapidly develops a fungus. In a few hours it is potentially septic and in a few days it is distinctly so and will produce suppuration. Lack of this knowledge is the cause of an existing belief that cocaine wounds do not heal well. It is conceivable that a solution of pure water might interfere with wound healing by swelling the tissues from inhibition, but when the law of osmosis is regarded and salt solution of proper density used to dissolve the drug, thus making it isotonic with the blood serum, it cannot interfere with the well-being of the wound. Cocaine solution may be boiled sufficiently long for sterilization without detriment to its anesthetic value. The crystalline form of the drug dissolved in a sterile fluid will not produce suppuration.

We have not used the solution advised by Schleich because the one just mentioned is simpler and satisfactory. A warm solution is more effective than a cold one.

*Technique.*—Much can be done by a personal calmative demeanor to quiet the nervous apprehension of the patient. A nervous, jerky surgeon will produce a correspondingly nervous, jerky patient. The position assumed by the patient on the table should be one of comfort and relaxation. For instance, if the arms are crossed above the head, the patient will be "fidgety" before completion of the operation from the tiresome position. To a nervous patient the click-click of the dissecting scissors may become unbearable.

If at the beginning, when everything is ready, the surgeon asks in pompous manner for a "knife," the patient's courage instantly vanishes. The word "bistoury" obtains the instrument desired and does not shock the patient; better still, an assistant who hands without asking. Even the initial prick of the needle must be explained. If after assuring the patient you suddenly and unexpectedly jab him with a needle, the subsequent argument that no man can call that real pain will only serve to convince him that your idea of pain and his do not agree. Observing the total sum of these little points makes big surgery under local anesthesia possible.

The line of skin incision is infiltrated throughout its extent. It should be sufficiently tight to hold the local anemia for an hour or more. The depth to which the needle is plunged in the skin is important. The highly differentiated end-organs of the sensory nerve are superficial. When the needle point lies true it can be seen from the surface. The skin incision should stop at the suprapubic skin fold. Downward traction will give abundant space for operative work, and the venous plexus in the mons veneris is avoided. Pain results whenever a surface blood-vessel is divided, and this is multiplied by each grasp of artery clamps and ligature. These repeated twinges occur at the *beginning* of the operation. There is a wide difference between pain at the beginning and pain near the end of operation. One destroys the patient's confidence in promised immunity, the other is borne with equanimity because the termination is at hand. The needle should be passed through the anesthetized skin and the fascia and the solution infiltrated around the external ring. The terminal branches of the ilioinguinal nerve lie in this situation. There is no necessity of waiting for the cocaine to take effect, but immediate incision down to the external oblique muscle. If the layer of subcutaneous fat is thick, Mata's massive infiltration is necessary before the skin is incised. Fat cannot be edematized after the skin incision. A solution of 1 to 10,000 cocaine may be used for the purpose.

The aponeurosis of the external oblique requires no anesthesia. Over the situation of the underlying internal ring the aponeurosis is incised. Before carrying this incision into the external ring the flaps are retracted sufficiently to expose the ilioinguinal nerve. This is cocainized at the highest exposed point by injecting the trunk with a few minims of the stock solution. The incision can now be carried painlessly into the external ring and the flaps reflected to full exposure of the shelving process of

Poupart's ligament outwardly and the conjoined muscle and tendon towards the median line.

Search for the iliohypogastric in the situation named can now be instituted. As stated, it is not always found; it is at times small and inconsequent: finally, it may be absent. If found and cocainized it greatly assists towards painless operation. If search is fruitless the margins of the internal ring and adjacent substance of the conjoined muscle are infiltrated with the 1-10 of 1 per cent. solution. Along the central line of the long axis of the protrusion a line of infiltration with the same solution is made. This line of infiltration is specially needed if the iliohypogastric is not found. A clean incision with scissors on this line is carried through hernial coverings to the sac. The ability of the patient to cough at request and define the sac makes this dissection safe and avoids the unsurgical blunt dissection.

The sac is now opened and the contents dealt with as needed. Trendelenburg's position is invoked to retain viscera within the cavity when possible, as it gives pain to crowd a pad into the peritoneal cavity. The neck of the sac is infiltrated, dissected away from the underlying cord, ligated, and amputated. The genitocrural is now sought, and if found and cocainized the operation can be completed in any manner the operator prefers without additional cocaine and without pain. If the nerve is not found the sac is dissected away from the cord by clean snips of the scissors from above downwards, and the operation completed *secundum artem*. It is believed by some surgeons that no harm can come from leaving the sac fundus *in situ* and by others that the integrity of vas deferens and testicle is safeguarded by at least leaving that strip of the sac that is intimately applied to the cord.

Operation on the female is easier than on the male, the round ligament being less sensitive than the cord.

If in the future transplantation of the cord is abandoned as of no value in preventing recurrence, the radical cure of inguinal hernia will be strictly one for local anesthetis.

9 East Thirty-ninth Street.

## THE ETIOLOGY OF TABES; ITS SOCIAL, LEGAL AND THERAPEUTIC CONSEQUENCES.

By FEODOR VON RAITZ, M.D.,

NEW YORK.

When, about sixty years ago, German physicians began to recognize tabes dorsalis as a distinctive disease, the question, what causes tabes, grew with that recognition; and, as at that time, syphilis was not under therapeutic control, its pathology and clinical aspects offered plenty of opportunity for observation and study. For this reason, those familiar with syphilis in its various phases, found no evidence which permitted them to make it responsible for tabes.

About thirty years later, French physicians, however, began to consider syphilis as a cause of tabes, and Fournier finally pronounced it as *the* cause. But, as the pathology of sypnilis did not support his statements, his views were considered idle theories, until Erb, a few years later, came to his support. Since then the syphilis theory has grown and appears accepted to-day.

But, while the etiology of tabes appears to be settled, there are a great many earnest observers who ignore syphilis as its cause, and some of them raise their voices from time to time in opposition, arguing that more than one factor is responsible for tabes.

The apparent establishment of syphilis as the cause of tabes is, therefore, not a natural consequence of progressive science, built on pathological facts, but a result of dogmatic ruling.

Dogmatism in medicine is, however, losing its influence more and more, and physicians of all countries cease to follow blindly the opinions of others, no matter how high their professional standing may be; and they begin to see that tabes is an important disease, not alone from a medical, but also from a legal and social viewpoint. They realize that persons afflicted with tabes are branded as syphilitics, which robs them of the respect and sympathy of those they love, and, in case of accident, of justice and compensation. But, worst of all, this view subjects them to the antisyphilitic treatment, which destroys all chances for recovery.

Tabes in itself is an affliction deplorable enough; to add to it the stigma of syphilis is simply cruel. If it were a fact that syphilis caused tabes, the cruelty would be unavoidable, but as it is only a dogmatic dictum, without any basis, it is our duty to clear away every doubt, so as to prove or disprove syphilis as the etiological factor.

A few cases will illustrate the harm the stigma of syphilis works. R. M., a lawyer, was thirty-five years old when tabes began to show symptoms. He had a loving wife and three children, and was just beginning to reap the benefits of his professional labors. After the diagnosis of tabes was made, his wife, an intelligent woman, learned that her husband's disease was attributed to syphilis. She soon knew what syphilis meant, and turned from a loving, sympathetic wife into an enemy of the patient, despite all his protests of innocence. The poor woman suffered great mental agony and grew nearly insane, first, because her husband had been to her the personification of all that was good, and secondly, because she feared that her children might show consequences of syphilis. As time went on the domestic conditions of this family grew unbearable, and, finally, she took her children and left her husband. This patient asserts that he never had any sore on his genitals, nor any eruption, nor other symptom of syphilis, and that he never led a life of dissipation, but he did not deny that he had a urethral discharge, about fifteen years ago, which was treated and cured by a physician in about two weeks.

Mrs. E. R., when thirty-one years of age, began to show symptoms of tabes. She had then been married ten years and had two children. She also denied having had any symptoms which could be attributed to syphilis, but stated that when about eighteen years old, she had a small abscess on the vulva, which was poulticed in accordance with a physician's directions, and which disappeared shortly afterward.

Her husband, however, prejudiced by the professional opinions as to the causation of tabes, lost confidence in his wife. She now lives apart from her family, although well supported by her husband.

J. L., a plumber, twenty-nine years old, while working in a building during construction, fell about twenty feet and landed on a heap of rubbish in the cellar. He felt somewhat dizzy and his left shoulder was a little sore, but after resting a while he felt better and attempted to work. He was, however, not able to do anything on account of a sense of weakness and nervousnes, which almost prevented him from walking. He was assisted to a street car and went home. The next day was Saturday, and as he still felt weak and nervous he did not go to work before Monday. For a few days he was, to all appearances, as well as ever, but although he did not feel well, he continued to work, believing that he would

overcome the weakness. After about two weeks, he began to feel unsteady on his feet and grew gradually worse, showing locomotor ataxia and abolishment of reflexes. Inside of six weeks all reflexes below the waist line were abolished, but his eyes remained as good as ever. The patient, upon the advice of his physician, had made a claim for damages, and an accident insurance company, stepping in for his employer, sent a physician who pronounced the condition as tabetic, entirely unconnected with the fall, and due to syphilis, which the patient admitted to have had about eight years previous. The patient's physician did not consider the case tabetic at first, but an injury to the spinal cord. The insurance physician, however, succeeded in convincing him that it was tabes, due to syphilis. The patient, in consequence, accepted a trifle as a compensation for an injury which left him a cripple for the rest of his life.

Those who accept syphilis as the cause of tabes have no difficulty in finding syphilitic evidence in everybody who has tabes. If a person admits having had syphilis, no further proof is necessary; if syphilis is denied, every disturbance at the genitals, no matter whether it be a specific of a simple urethritis, a vulvar abscess or abrasion, a chancroid or a simple sore, is sufficient evidence of syphilis. If disturbances at the genitals are denied, then any eruption on any part of the body furnishes the proof. And if everything is denied, then the "benefit of the doubt" is a convenient support to establish syphilis, and so the hundred per cent. is accounted for and tabes stands as a postsyphilitic disease.

The actual cause of any disease is, however, not determined by opinions and theories, but by pathological facts alone, and these facts must give such evidence as proves that the disease under consideration rests on them.

To ascertain whether tabes is a postsyphilitic disease, let us look at the pathology of syphilis first, as far as it can have any bearing on tabes. For this reason we need not consider the nature of the syphilis poison, nor any of the various pathological conditions outside of the nerves, cord, and brain.

Since the successful therapy of syphilis has been established, post-mortem examinations of bodies dead from syphilis are unknown, and whatever knowledge of the pathology of syphilis we possess is handed down to us by pathologists of days prior to our present antisyphilitic measures. I believe that no one of those who make syphilis responsible for tabes has ever examined a syphilitic cadaver, perhaps not even a tabetic cadaver, and all that modern writers on tabes say of syphilis is quotation.

We, however, still meet, now and then, badly neglected cases of syphilis, presenting abscesses, fistulæ and severe cachexia which, if observed studiously, and for a long period of years, prove very instructive. It also sometimes happens that a syphilitic dies from other causes, and that a studious physician gets hold of the body with a view of studying syphilitic degeneration, but how seldom that is, we all know. But, insufficient as our knowledge of the pathology of syphilis is, we know enough to make it practical for the comparison with tabes.

As stated above, for our purpose we need to consider syphilis only as we find it in the nervous system, but wherever found it presents itself in two forms. First, the exudative, which is due to transudation of the pathological products from the blood-vessel walls at points of least resistance. This form is always diffused, even if it appears in lumps or tumors, and it furnishes what should be called gumma. Secondly, the productive type, which is due to cell-proliferation, and furnishes the syphiloma, which is never diffused, even if it does not appear as a lump or tumor.

Despite this absolute difference, everybody speaks of gumma and syphiloma as if it were one and the same thing. Moreover, gummata appear prior to syphilomata when the virus is most potent, while syphilomata appear later, as a consequence of perverted nutrition.

But whether gumma or syphiloma, and wherever situated, both give pressure symptoms, if they give symptoms at all, but no symptoms of nerve degeneration. And, after their absorption, all symptoms disappear. When now, after a number of years, tabes does develop in any individual who has had syphilis, what pathological facts remain to prove that syphilis is the cause?

Moreover, syphilis everywhere presents itself with absolute clearness as a blood disease, without any tendency to cause degeneration, except by its productions and exudations, and by the cachexia. If the syphilis virus had a degenerating tendency on the nervous system, this would manifest itself at the time when the virus is most potent, but not years afterward. And, if antisyphilitic therapeutic measures are potent enough to overcome all activity of syphilis, why then should we expect any syphilis virus, the nature of which is to act as long as it exists, to remain dormant in the system for years?

Has anybody ever found dormant syphilis virus? But suppose the syphilis virus could remain latent, it could be so only when hermetically encapsulated, and it could grow active only by rupture of the capsule. To speak of dormant syphilis virus is so absurd that nothing more need be said about it. Furthermore, if tabes were a postsyphilitic disease, then the antisyphilitic therapy would have a curative effect on tabes, but it is a fact that such therapy in tabes does nothing but harm.

Examinations of the cord and brain of tabetics show no gummatous deposits but the characteristic degeneration of nerve fibers. The degeneration of the spinal sensory nerves is simple atrophy, due to cessation of function, and brought about by the degeneration of the nerve fibers in the cord.

Whether the nerve fibers of the central system degenerate first, or in consequence of the degeneration of their ganglionic cells, is not material for an argument against syphilis. The nerve fibers and ganglionic cells degenerate, however, one by one, leaving sound fibers and cells between, until finally, as the disease progresses, not only the whole parenchyma of the posterior columns, but also the whole spinal cord degenerates. This is all that needs to be considered to prove that the pathology of tabes is as different from that of syphilis as is tuberculosis from rheumatism, and that tabes is not a metasyphilitic disease.

Now, as syphilis does not prove to be the etiological factor of tabes, quite a number of physicians have begun to doubt the syphilis theory, and a few have expressed their opinions, holding that there must be factors outside syphilis which cause tabes. To find them, we must remember that tabes begins either in the nerve fibers, or in the ganglionic cells of the central nervous system, or in both. What agents are potent enough to induce such degeneration? We know that mental strains affect the power of reasoning, and also that physical strains affect the cells which govern locomotion and sensation. Physical strains, therefore, call for our consideration.

Inquiry into the previous histories of tabetics teaches us that many tabetics have practised coition excessively, and that, in time, the coitus has caused peculiar, even painful sensations in the genitals and

in the head. Others, who, to prevent fecundation, have practised interruption of the sexual act by depositing the semen *ante vulvam*, and other still, who have practised masturbation excessively, have experienced the same sensations.

The sexual center lies in the lumbar portion of the cord. Sexual impulses descend from the brain to the center or ganglionic cells in the gray matter, and from those cells, along the nerve fibers of the posterior columns, through the posterior nerve roots to the genital apparatus. Sexual sensations ascend from the genital organs in a reversed order to the brain. When sexual impulses force the concerned ganglionic cells too often, and for too long periods of time, they lose power; and if the state of exhaustion continues without time for physiological recuperation, degeneration is the final result. Sexual sensations travel along separate roads upward to the brain, and a too frequent descent of impulses and ascent of sensation will, therefore, exhaust separate ganglionic cells in the cord and in the brain.

After the death of ganglionic cells the attached nerve fibers grow useless, degenerate and cause atrophy of the nerves leading to the periphery. The tabetic process, in cases due to sexual excesses, starts, therefore, in the ganglionic cells of the cord and brain. This class of tabetics furnishes what might be termed the cerebro-cerebellar type, with early ocular, visceral, and bulbar symptoms.

We know, further, that diphtheria, cerebrospinal meningitis, and typhoid fever affect the nervous system, and that they are often followed by loss of reflexes and symptoms of paralysis. As yet no prolonged observations of such sequelæ have been made after the original disease has subsided, and after the paralytic symptoms have ceased to be apparent. The history of some tabetics informs us that they have had one or more of these diseases, that their periods of convalescence were prolonged, and that they were never as strong afterwards. To make these diseases responsible for tabes, no chain of evidence can be established. And yet, the fact remains that they cause, in a number of cases, nervous symptoms which are not due to peripheral, but to central intoxication. This proves, even if this intoxication is only temporary and leaves apparently no impairment of function, that the toxins of these diseases are capable of affecting the central nervous system. Nerve substance is very delicate, and it is, therefore, quite probable that some spinal cells have been left weak, so as to break down at a later time, when their functions are called upon beyond their power of endurance.

All matter is chemical, and life, in its various forms of existence, is nothing but the result of chemical action. So also is the human body nothing but a compound chemical mass, built by certain elements. When substances, which are not used by nature in the construction of the body, enter it, they will, sooner or later, more or less, according to their physical properties, to the amount introduced and to the period of time during which the offense lasts, cause symptoms of harm. Toxins which result from the decomposition of organic matter, are poisonous in varying degrees. And, although the elements which compose them are not foreign matter, having been used in the construction of the body, the process of decomposition forces new chemical combinations, the products of which become foreign substances. The body is ever active to rid itself of all that is, or becomes, a foreign substance, but, when the system is not strong enough to eliminate the toxic substance quickly, the power of resistance weakens, and fails to check the diffusion of the toxin, and consequences show themselves immediately, or in after effects and predispositions to other troubles, which are not always recognized as such. Inorganic toxic substances affect the body and are affected by the body in the same way.

We have, therefore, two classes of toxic agents which may cause tabes or predispose to it. If we admit organic toxins as a possible cause, the syphilis poison is one of them. To ascertain whether any of them is indeed an etiological factor of tabes, remains for the future, but that syphilis does not cause tabes is already proven by the pathological and therapeutic divergence of both diseases. Whether inorganic poisons can predispose to or cause tabes, also awaits answer in the future. Mercury, however, stands suspected already, as many tabetics, who have had syphilis, have been treated with mercury.

Injury to the cord, as an etiological factor of tabes, has of late arrested the attention of unbiased observers, and there is sufficient evidence to force serious consideration of those cases whose history points to accidents after which tabetic symptoms appeared. Injury to the cord may occur without any external evidence, and, as a matter of fact, seemingly trivial accidents are, at times, followed by tabes. Severe traumatism to the spine may cause instantaneous partial or total, transient or permanent paralysis below the level of the injury, but no symptoms of locomotor ataxia, while a simple fall or sharp twist of the spinal column, leaving no external evidence of injury to the spine, and no immediate symptoms referring to the cord, may induce locomotor ataxia. When, after a fall, symptoms appear gradually, they are not understood until locomotor disturbance sets in; and even then serious attention is not paid to them, but liniments and antirheumatic remedies are employed until a competent man makes a diagnosis of tabes. If this physician holds to the syphilis theory, he will, under all circumstances, find that the patient has had syphilis some time ago, no matter whether he has had symptoms of the disease or not, for, if all evidence fails, the "benefit of the doubt" covers every lack of information. The fall is thrown out as an etiological factor as soon as mentioned, because no explanation of how a fall can cause tabes has, as yet, been offered. Some, however, admit that a fall, while not the cause of the condition, might have hastened the progress of the disease, which was present before the fall.

How a simple fall can cause injury to the cord and subsequently tabes is, however, not difficult to understand. We know, when a bloodvessel is subjected to tension and torsion, it loses its elasticity by overstretching or rupture of the muscular fibers of its walls. When a person falls, he will, before the body reaches the ground, try to save himself by throwing his weight in the opposite direction. This motion is carried out with great suddenness and with as much power as the person has at his command. The spine is then bent and twisted at the point of greatest flexibility. The anatomical relations of the spinal column allow the greatest freedom of motion in the lumbar spine, and there the center of gravity of the lower part of the body, in its downward course, is suddenly met by the weight of the upper part of the body in its opposing direction, thus mitigating the impact of the body with the ground. To oppose the falling of the body still more forcibly, the arms are suddenly thrown out in the opposite direction, and according to the degree of pronation of the upper body, necessary to oppose the fall, a corresponding bending and twisting of the spinal column takes place, during which the bloodvessels are stretched and twisted. If the degree of tension and torsion is greater than the elasticity of the implicated arterial walls can endure, the mus-

cular fibers are damaged and the walls may, at one or more points, collapse and obliterate. The portion of the cord concerned will now, sooner or later, suffer want of nutrition, in proportion to the number or importance of the nutrient arteries involved, and corresponding symptoms of degeneration become, more or less, apparent. The process of degeneration once started, has a tendency to progress, unless checked by forced nutrition, which, no doubt, often enough, takes place in strong individuals. Quick restoration of nutrition may take place, leaving, after a shorter period of weakness, no trace of disability, and giving no information of the danger just escaped. After such injury the spinal nerve fibers or ganglionic cells, or both, may be affected, as this depends on where nutrition ceases, and the first symptoms which present themselves are disturbance of locomotion. This class furnishes the motor type of tabes.

Now, when sexual excesses, toxic agents, and traumatism claim consideration as etiological factors of tabes, it can readily be understood why the pathological anatomy, the symptoms, and the rapidity of the course of this disease vary so greatly.

That traumatism is being recognized as an etiological factor of tabes, is proven by a few cases awaiting compensation for damages by the courts, but those physicians who are overcome by the syphilis theory deny the existence of traumatic tabes, without having any basis whatever upon which to prove the existence of syphilis, or to deny traumatism as a cause. It is simply their opinion, or the opinion of others which they offer. But opinions are worthless, no matter by whom expressed. Facts alone carry weight.

About four years ago a woman was thrown out of a trolley car; she was unconscious for a little while, and was then brought home by the assistance of fellow travelers who witnessed the accident. There were no visible signs of injury anywhere on her body, but she complained of headache, nervousness, general weakness, and some pain in her right shoulder. After a few days had gone by without improvement in her condition, she entered my office, complaining mostly of vague pain in the shoulder or back. She could not say where the pain actually was. My examination was negative, and I attributed her symptoms to shock, which, as I then thought, would disappear under rest and other appropriate measures in a short time. A lawyer had taken hold of the case, and I was asked what amount would compensate the damage. I recommended one hundred and fifty dollars as a reasonable sum. The patient went, according to my advice, for fourteen days to a quiet place in the country, and when she returned to my office I was astonished at her appearance and gait, and I found then that her spinal cord was injured. Meanwhile, a suit for one hundred and fifty dollars had been instituted. I, therefore, informed the patient of the nature of her injury, and also that the suit should be withdrawn, and all legal proceedings stopped, until the nature and the consequences of the injury could be ascertained. The railroad company engaged a prominent neurologist, whose opinion then was that the patient had sustained injury to the cord, and he advised compensation and settlement. At first the symptoms were vague, but soon they grew markedly tabetic. The case being of great interest from a scientific standpoint, I wished that the company's specialist might have every opportunity of observing the patient, and I instructed her to go to him as often as he desired, despite the fact that my patient's lawyer objected to my professional motives, as he feared that the physician for the company, might misuse the trust I placed in him for the benefit of the company. The case is now in the supreme court with a claim for fifty thousand dollars. This patient represents a pure locomotor type of tabes and did not have syphilis.

Another case of traumatic tabes, also that of a woman, Mrs. B., thirty-six years old, came shortly afterward to me and stated that, about eight months before, she had slipped on a banana peel and had fallen on the sidewalk.

As this case of Mrs. B. also represented the locomotor type of tabes, due to traumatism and without a history of syphilis I, led by professional motives, placed her also at the disposal of the same specialist, instructing her to allow him to observe her as much as he pleased and as long as it was convenient to her. After a few months the patient ceased to come to my office, and when I received no answer to my inquiry, I went personally to see her, but found that she had left her boarding house for quarters unknown. The lawyer of Miss H., who sued for $50,000 damages, holds that Mrs. B., was "spirited" away to prevent her appearance in court, as she, not being a syphilitic, and, having no claim for damages, could prove to be a great blow to the defense and to the syphilis theory as a cause of tabes.

The plumber, whose case I mentioned before, although he has a syphilitic history, represents also traumatic tabes of the locomotor type.

An iron constructor, while working at an elevator shaft, bending far over, and having the lower half of his body resting on the adjoining stairsteps, bent too far and began to fall. At the very beginning of the fall, his arms being in the frame work of the iron structure, he took hold of what was within his reach, but the lower part of his body, below the waistline, fell down and twisted to the left side and backward. A workman just below him, with the assistance of others, took him down and laid him on the floor. He was semiconscious for a while, but recovered from the shock after about one hour and went home, as he did not feel like working. He had, as he stated, "wrenched his back rather a little too much for comfort," and thought he would take a rest. This man intended to work next day, but felt so weak and nervous that he remained at home. For a few days he had his back rubbed with liniments and felt better, but he could not walk down stairs without holding to the railing, and he then grew very nervous. His gait slowly became more and more unsteady, though he complained of nothing but nervousness, lack of power, and impaired sensation in his legs, and, for a few weeks after the accident, of peculiar headaches. Three years have gone by. The patient's eyesight is perfect, his arms are strong, but his reflexes are lost below the umbilicus. He feels quite comfortable, as the therapeutic measures to which he was and is subjected are based upon the pathological facts of his case, which exclude antisyphilitic treatment, and all measures which lack indication.

The fifth case is that of a man who jumped from a wagon while his horse was running away. He landed on his left heel with great force, was twisted somehow, and fell on his face. He had abrasions on his face, hands, and knees, which did not mean much, but the heel gave trouble for four months, and he has yet, nineteen months after the injury, at times, peculiar sensations in his heel and lower extremities. After the fall he had but slight headache and was not very nervous, and whatever attention he needed was to his left heel. A few weeks later, however, he began to feel that his legs did not follow his will as usual, and his reflexes were impaired. To-day he is quite comfortable and goes to

his business, although he has to use a cane to steady himself occasionally, especially when he is in a crowd. For a time the ataxia was serious, but he grew gradually better, until he now shows very little locotomor disturbance, and it looks as if he were going to get well.

These few cases of traumatic tabes occurred in individuals who were physically sound and strong before the injury. They all represented the locomotor type.

I have had two more cases of the locomotor type, but no history of any accident to which the condition could be attributed, although both of them stated that they had bent and twisted their bodies often enough, and that they have had backaches. It is, therefore, not impossible that in both these cases injury to the cord may have occurred. And again, there may be other, yet unknown, etiological factors which cause this type of tabes.

That sexual excesses alone can gradually predispose to tabes, is theoretically clear enough, but I have not had a case with a history of such excesses, without a concomitant history of diphtheria, typhoid fever, or some other disease which might have been cerebrospinal meningitis or inflammation of the cord. Miss Ida E., was forty-two years of age when I was called to her bedside in October, 1897. Other physicians had treated her, and one had seen her shortly before I was called. When I saw her first she could not stand on her feet, not even while holding to the end of the bed. All reflexes were totally abolished, the bladder did not act, and there was a peculiar cystitis. The rectum had no sensation. Girdle sensation was very sharp and there were frequent attacks of oppression in the chest, which almost suffocated her, and caused severe hysterical outbreaks with suicidal impulses. Darting pains in her lower extremities caused much suffering. At the waist line, all around the body, was an area, about six inches broad, studded with warty, brown eruptions. After I had stopped the potassium iodide and strychnine, and after she had improved enough to be more peaceful in mind, she gave answers to my inquiries, and admitted having practised masturbation from her early girlhood until shortly before tabes set in. At first, and for a while, she masturbated five or six times daily, and then gradually less. Her mother informed me that the patient had had diphtheria and typhoid fever. The patient also admitted having had sexual relations a few times when in her teens, but she never had any sore on her genitals, nor any eruptions, save those at the waist line, which began to break out shortly before she experienced the first pains in her lower extremities; nor did she have any other symptom which could refer to syphilis. As soon as tabes was recognized she was put under potassium iodide, and forthwith she grew worse, and as soon as I stopped it, she grew better. Because she had tabes, the attending neurologist held that she had had syphilis, no matter whether it could be proven or not. What was the cause of tabes in this case? To answer syphilis, is absurd, but was diphtheria, typhoid fever, or the excessive masturbation the real cause?

M. H., 46 years of age, a merchant, married, had three sound children, the oldest fifteen years, the youngest nine years of age. He came under my observation in 1894. He was also treated with potassium iodide by various physicians and grew steadily worse. He had no syphilis, but had practised masturbation excessively from his early boyhood to his marriage. His mother informed me that he had had diphtheria and all children's diseases, and that he, as a child, was peculiar and very quiet. His first tabetic symptoms were disturbed locomotion, without pain in the lower extremities. He had no thoracic nor abdominal symptoms, but bulbar symptoms appeared later in a manner strikingly similar to general paresis. In this case, also, syphilis was out of question. What caused the tabes?

G. H. F., a patent lawyer, forty years of age, married ten years, no children. Had diphtheria in 1900, which was followed by loss of reflexes and locomotor disturbances. He did not have syphilis. Under judicious treatment, without potassium iodide, he grew gradually better, and is to-day practically sound, although the reflexes are still somewhat impaired and he has to hold to the balusters when going downstairs. His pupils do not react normally, but he sees well. In this case diphtheria appears as the cause of tabes.

R. S., 27 years old, a merchant, single, came in 1898, from Texas to New York City to recover from the effects of malarial fever, which left him weak. After he was in this city for about six months he grew ill with typhoid fever, from which he recovered. Before he went to Texas, he was a strong fellow, but malaria and typhoid fever had reduced him to a physical wreck. As the typhoid fever kept him in bed for six weeks, nothing was thought, for some time, of his inability to use his legs normally. Gradually, however, his locomotion grew worse instead of better. When I was called in I found loss of reflexes in the lower extremities and a generally broken down nervous system. In a confidence-inspiring manner, I stated that the patient's condition was not as serious as it appeared, and that, while the recovery would be slow, it would be perfect. This assertion had an almost magic effect on the patient, and the members of his household. It lifted the cloud and assisted my therapeutic measures. The nutrition of the body was my sole aim, which, while difficult, was effected by external and internal agents, according to appearing indications. This patient improved and is now practically well, but there is still some delayed sensation in the lower extremities, and there are no patellar reflexes. He had no syphilis.

George M., a cigarmaker, 43 years of age, married fifteen years, and has two sound children, came under my observation in 1901, with pronounced symptoms of tabes. He denied syphilis and every venereal disease, but stated that, as he was not earning much money, and as two children were all he could afford to rear, he interrupted the sexual act by withdrawing. He stated also that he had been very sound all his life, and had not even had any children's diseases. Before he came to me he was subjected to antisyphilitic treatment and grew slowly worse. After I stopped this treatment he improved and has held his own ever since. In this case there is nothing to which to attribute tabes except the "withdrawing," which he practised excessively, as both he and his wife were very amorous, or the excessive sexual function in itself.

R. L., 44 years of age, a hotel keeper, married eleven years, no children, contracted syphilis at the age of 25, and was put under antisyphilitic treatment, without delay and for about three years, although all symptoms of the disease disappeared within one year. He always was well and strong before his twenty-fifth year, but never regained his strength after the syphilis, although he had no special symptoms to complain of. When about forty years old, vague sensations in his legs began to appear, which for some time received no special attention; later on, however, he was treated for rheumatism. Two years after the first tabetic symptoms, locomotor disturbances set in, which grew gradually

more marked, and forced the recognition of tabes. Ocular symptoms were present also, and in 1903, when he came under my observation, bulbar symptoms began to appear. Four months later he died, and his death-struggle was similar to that of general paresis. Within one year this patient outgrew the syphilis, but he was treated for two more years by mercury. To what was tabes due in his case?

If syphilis is the cause of tabes, then every person who has had syphilis to a marked degree, and who was not treated by mercury, should develop tabes, but this is not the case. On the contrary, it appears that syphilitics who have not been treated by mercury do not develop tabes, while some of those who have been subjected to this agent are afflicted by it. And, retrospecting the medical history of pre-mercurial ages, we find that syphilis was then, in proportion to the existing population, more prevalent than now, and that, despite the lack of mercury, tabes was not known. When physicians began to employ mercury against syphilis, symptoms, which gradually led to the recognition of the pathological entity of tabes, began to appear. Tabes appears, therefore, as a sequela of mercury.

F. S., a salesman, contracted syphilis in 1892. As he had previously had various attacks of urethritis and also ulcers on his penis, he considered himself competent to take care of the sore at the glans penis. He cauterized it with nitrate of silver and kept it clean, and it healed in a short time. When, after a while, eruptions broke out all over his body, he took hot sulphur and salt baths, kept his bowels open, and held to a plain diet. The eruption disappeared within about four months and he believed himself cured. Gradually, however, he noticed nodules in various parts of his body, and abscesses developed. He then looked for competent treatment, and in about two years after the infection, 1894, he came under my observation. He was then pale and emaciated, and had two discharging abscesses, the sinus of one opening in the perineum, the other in the right side of the chest. After six months I discharged him from active treatment, but kept him under observation for about one year. Ten years have gone by, and the patient states that he feels well. If syphilis causes tabes this man should have it, for he represented a severe case.

Considering now the few facts, which experienced physicians know to be as presented here, we must conclude: (1) That there are various factors which cause tabes, and (2) that syphilis is not proven to be a cause of tabes.

Consequently, even if a person afflicted with tabes is proven to have had syphilis, it does not follow that tabes was caused by it; and it is obstructive to science and injurious to public welfare to pronounce a person, because he has tabes, a syphilitic.

1 West One Hundred and Second Street.

## EYE DEFECTS ASSOCIATED WITH THE DEVELOPMENT OF PUBERTY.

By K. K. WHEELOCK, M.D.,
FORT WAYNE, IND.
PROFESSOR OF CLINICAL OPHTHALMOLOGY AND OTOLOGY IN THE FORT WAYNE COLLEGE OF MEDICINE.

For seven years it has been in my mind to present my observations upon a certain class of cases, occurring in children from eight to fourteen years of age, characterized by great loss of vision, marked limitation of the visual field, and an eye ground varying from normal to frayed blood-vessels with a "shot silk" fundus, while the general health of the patient has been good.

To my mind the best explanation of the phenomena is to be found in changes in the optic nerve and blood stream, incidental to the development of the reproductive organs. This position is the more certain in my mind since treatment is of little avail, and recovery is not complete until the caramenial function has been established in the girls, and the seminal function in the boys. My observations were carefully made, but whether the hypothesis of dependence upon changes incidental to the prepubertal condition was a valid one, made me hesitate to present this physiological change as the cause of a pathological condition. Therefore, letters under date of June 18, 1904, were addressed to Drs. Gruening, DeSchweinitz, and Gradle, with the result of still causing me to hesitate in presenting the report. But since Dr. L. Webster Fox's paper before the Ophthalmological Section of the American Medical Association, has appeared in the issue of the *Journal of the American Medical Association* for January 7, 1904, and since the details of his cases are similar in all respects to my own, with the exception that my cases never received any benefit as regards the restoration of the field of vision from treatment, I concluded to present them together with the etiological hypothesis as suggested in the title.

It is to be understood definitely that the cases were not cases of chlorosis. None of the subjective or objective symptoms of chlorosis were present. The patients were all well nourished children, in good social conditions, such as obtained in a small town, where the general hygienic surroundings were unexceptionable. None of the children were pale, ill-nourished, flabby, hysterical or neurasthenic. Their complaint was simply that they could not see. Neither was their defective vision the result of errors of refraction, since the same relation of defect was maintained for distant as well as near vision, and for the additional reason that any and all glasses added nothing to the degree of sight. Furthermore, none of my cases were, when first seen, beyond the age of twelve years, which is the minimum age limit laid down by Osler for chlorosis.

Case I.—My first case in which I recognized the possible relation between the pathological state and the etiological factor of pubertal development was seen February 14, 1898. Girl, age, 8 years, blonde, from a neighboring village; social conditions good. She was well nourished and complained of some headache and inability to ride her bicycle. At the age of seven years she was very expert, but now cannot ride owing to her inability to see objects in the general field of vision. Family history good. R. E. S. 20/80; Jaeg. No. 6. L. E. S. 20/80; Jaeg. No. 6. Sight not improved by glasses. Examination of the field showed it reduced almost to point of fixation. Colors almost centrally perceived. On ophthalmoscopic examination no change was noted in the fundus except that the veins might be a little fuller than normal and the macular region somewhat paler than normal. Dr. Drayer examined the blood and reported: white cells 300,000; polynuclear leucocytes; few microcytes; red cells 2,560,000; urine alkaline: sp. gr. 1,018: no albumin, no sugar, phosphates abundant.

Patient was placed at once upon strychnine and iron, while cascara was exhibited to regulate the bowels.

February 21.—R. E. S. 20/80: not improved; Jaeg. No. 6; L. E. S. 20/80: not improved; Jaeg. No. 3. Blaud's pills were administered.

February 23.—Blood examination. Red cells 3,986,000; white cells 160,000, few poikilocytes, polynuclear leucocytes and a few microcytes.

March 1.—R. E. S. 20/50: not improved; Jaeg.

No. 4; L. E. S. 20/50: not improved; Jaeg. No. 4. Field unchanged.

March 22.—R. E. S. 20/50; L. E. S. 20/50. Strychnine, gr. 1/30 t. i. d. ordered.

April 21.—Vision same as March 22 and field narrowed to original area and even narrower.

Patient passed out of my hands and subsequent inquiries elicited the fact that she was still having defective vision two years later. There was no variation in the visual field, no reversal of the color sense and very little improvement in the sight after several months of treatment.

Case II.—Russel A., age 10 years. This boy was the son of well-to-do parents, and his general appearance was that of a healthy child. He first consulted me January 10, 1898, when his visual condition was as follows: R. E. S. 20/20; L. E. 20/20; ophthalmoscopic examination nil. Complains of pain in the eyeballs and irritation of eyes in bright light.

Diagnosis: Follicular conjunctivitis. I saw him no more till October 14, 1898. He then complained of nictitation and twitching of the mouth, and defective sight. The general health seemed good and he seemed to be well nourished. R. E. S. 10/100: + 1.25D 16/40; L. E. S. 16/100; + 1.25D 16/40. Static equilibrium, Jaeg. No. 10 with either eye. I could not account for the disparity between close and distant vision under glasses, except on the basis of a high degree of hypermetropia. Paralyzed accommodation with atropine 1 per cent., with the result of no improvement in distant vision.

October 17.—Examined the field and found it reduced almost to point of fixation.

October 20.—R. E. S. 16/100: + 1.25D 16/50; L. E. S. 16/100: + 1.25D 16/70. Field reduced to central fixation for either eye for form and color.

November 11.—R. E. S. 16/50: + 0.75D 16/40; L. E. S. 16/50: + 0.75D 16/40. Field extended to about ten degrees. He was under the care of his family physician, who was administering iron and strychnine. After one year of continuous treatment he began to recover a normal field.

Case III.—B. F., girl, age 10. Well nourished and in fair general health. Consulted the writer on October 15, 1895, with the complaint of headache. Functional examination: R. E. S. 16/20: + 0.75D accepted; L. E. S. 16/40: + 0.5D = 16/20. Under atropine 1 per cent.; R. E. S. 16/40: + 1.25D = 16/20; L. E. S. 16/40: + 1.5D = 16/20.

October 18.—R. E. S. 16/100: + 1.25D = 16/30; L. E. S. 16/70: + 1.25D = 16/30. Field seems much contracted, whether actually or comparatively I do not know. Have any observations been made to determine the extent of the visual field in children? Observation of the case was continued till December 30, 1898, when the field was found complete. The test for vision continued to show 16/20 during all the time in which the field was much contracted. The child was under the care of the family physician, who had prescribed iron and strychnine. The vision remained good and the field complete in this case a year after restoration.

Case IV.—M. L., age 14, colored. May 22, 1904. Well developed girl; had not yet menstruated. R. E. S. 16/100; not improved, Jaeg. No. 12; L. E. S. 16/70: not improved, Jaeg. No. 9. Field limited almost to point of fixation. Prescribed strychnine and iron. Child continued under treatment for about one year, and passed from under observation not much improved.

January 14, 1905.—R. E. S. 15/15; L. E. S. 15/15. Field completed. Menstruation established.

Case V.—Delcie D., age 10. December 27, 1901. Came from neighboring town. Complains of eye-pain upon reading or use of eyes for close work. R. E. S. 16/30+: not improved; L. E. S. 16/30: not improved. Ophthalmoscopic examination showed a slight veiling of the fundus and the small arterial twigs were tortuous.

November 17, 1902.—Patient moved to town and was referred to me by Dr. Geo. W. McCaskey, who had been consulted on account of nervous symptoms. She complained of much headache and had very acute changes in circulation, so that the teacher sent her home one day fearing she was ill with scarlatina. R. E. S. 16/70; not improved, Jaeg. No. 9; L. E. S. 16/100; not improved, Jaeg. No. 9.

Dr. Rhamey reports that blood examination indicates leucocytosis. Strychnine and iron was prescribed. Was under galvanism by Dr. McCaskey and general treatment for over one year.

July 10, 1903.—R. E. S. 16/70+: Jaeg. No. 5, with difficulty; L. E. S. 16/70+: Jaeg. No. 5, with difficulty. Field contracted to ten degrees of point of fixation. Physically, the child is the picture of health. In November, 1902, the least exertion made the child very tired and she had frequent sighing respiration.

Case VI.—Donald D., age 10 years. Consulted me May 23, 1904, for defective vision. The teacher had complained that he could not see, and placed him on the front seat. The mother noted that he brought his book too close to his eyes and read indifferently. He had pain in the eyes when he read, which was undoubtedly due to the exertion caused by the attempt of an amblyopic eye to see. R. E. S. 15/70; L. E. S. 15/70. Field reduced to fifteen degrees of fixation. Boy seems healthy.

May 26, 1904.—Examination of blood by Dr. N. L. Deming, the family physician, shows red cells, 2,500,000; white cells 4,000; hemoglobin 47 per cent. A diagnosis of anemia was made from the blood examination. Examination of urine negative. My diagnosis was amblyopia, due to defective blood supply, coincidental to the prepubertal state. The family physician was directed to put the boy upon a full diet with plenty of outdoor exercise, together with strychnine and iron. This was done. I suggested that the eye trouble would not likely disappear till the seminal function was established. I did not see the patient again until February 5, 1905, when the following was observed: R. E. S. 15/70: Jaeg. No. 5; L. E. S. 15/70: Jaeg. No. 9. About this date, January 7, 1905, Dr. L. Webster Fox's article entitled, "Contraction of the Visual Field, a Symptom of Anesthesia of the Retina in Children," appeared in the *Journal of the American Medical Association*. In it he reported a series of cases so exactly similar to those which I had seen that I was very anxious to have galvanism applied as suggested by him, viz., the "voltaic alternative current," which consists in repeated reversals of the voltaic current, about two milliamperes, continued for five minutes. At the same time believing that the pathology rested upon the blood changes due to the prepubertal development, I told the parents that no beneficial results would be had from the treatment. Dr. L. P. Drayer made the application as directed and nineteen séances were had. The boy then left for Chicago, and I saw him for the first time after the galvanic treatment, on April 16, 1905. R. E. S. 15/70: Jaeg. No. 9; L. E. S. 15/100: Jaeg. No. 11. Strychnine with manganese was ordered. The fields were much contracted for form and color.

April 22.—R. E. S. 15/70: cyl. + 1.75D axis 90° + 0.5D = 15/40; L. E. S. 15/70: cyl. + 0.75D axis 90° + 0.5D = 15/40.

May 6.—R. E. S. 15/70: cyl. + 1.25D axis 100°

= 15/20. Jaeg. No. 2; L. E. S. 15/40: cyl. + 0.75D axis 90° = 15/30. Jaeg. No. 1.

May 8.—Dr. Drayer again examined the blood and found hemoglobin, 85 per cent.; white cells, 12,000; red cells, 3,800,000. The field had shifted in form and varied in extent, but had not improved in area with improvement in vision.

Case VII.—June 7, 1905.—E. L., age 11; child of a physician. Was brought to me because the barber-optician who was changing her glasses every two or three weeks, wanted to put on a still stronger pair.

R. E. S. 15/100: + 1D = + 0.75D axis 90 = 15/30; L. E. S. 15/70: + 1.25D = 15/30. Jaeg. No. 3 with either eye. Blood examination by Dr. Rhamey. Red cells, 4,500,000; white cells, 15,000; hemoglobin, 75 per cent. Diagnosis, leucocytosis. Prescribed iron, manganese, and strychnine.

July 12.—R. E. S. 15/30 +: + .75D = 15/20: Jaeg. No. 1; L. E. S. 15/20 +: + 0.75D = 15/20. Jaeg. No. 1. Field contracted to 20°.

Two other cases have come under my observation, in one of which a boy, about fourteen years of age, consulted me for defective vision in which there was no lesion of the fundus, and in which the vision was greatly reduced both for distance and the near point. Glasses did not improve the sight, nor was he helped by treatment. The field was not examined at that time. The boy went through school greatly handicapped and is now a teacher. Recently, I examined his eyes and found his vision reduced to 16/50 for either eye, reading Jaeg. No. 3, and marked limitation in the field.

Another case was that of a young woman, married, age twenty years. She consulted me for defective vision, which came on her as early as the tenth year. Her sight is reduced to R. E. S. 15/70, L. E. S. 15/100; field very narrow and the papillomacular section of nerve very pale. Neither of those cases was materially improved by hypodermic injections of strychnine, gr. 1/15, twice daily. I do not doubt but that many cases of so-called congenital atrophy of the nerve are developed from conditions of defective blood supply incidental to the prepubertal state.

In conclusion, I would call attention to the following points:

1. Defective vision for distance and reading.
2. Limitation of field for form and color.
3. Age of patients eight to ten years.
4. Absence of chlorosis.
5. Absence of hysteria.
6. Blood examination showing leucocytosis.
7. Recovery of normal sight both for reading and distance with much contracted field.
8. Treatment addressed to restoring hemoglobin and nerve force best accomplished by iron, strychnine, and manganese.
9. Complete restoration of sight and field occurring only after the establishment of the menstrual function in the female, and the seminal function in the male.
10. There may be some relation between this condition and chorea, as suggested in case three.

---

**An Epidemic of Glandular Fever.**—Chicago physicians have had many cases of a glandular fever in children which resembled a streptococcus sore throat, but was accompanied by sudden and marked swelling of the cervical glands, signs and symptoms of a general sepsis, swelling of the spleen and liver, and in severe cases acute nephritis. Influenza bacilli were found on the tonsils, as well as pus cocci. Heliodor Schiller reports cases in *The Journal of the American Medical Association* and discusses the diagnosis. Diphtheria and tuberculosis were easily excluded. No case was fatal, in spite of the serious character of disease and complications in some of the cases.

## DIAGNOSIS IN CARCINOMA OF THE STOMACH.

By EDWARD F. McINTOSH, M.D.,
NEW HAVEN, CONN.
INSTRUCTOR IN DISEASES OF THE STOMACH AT YALE UNIVERSITY.

Symptoms of cancer of the stomach vary greatly. In some cases there are no symptoms whatever save failing health; and only the postmortem, reveals the malignant disease which has so insidiously done its work; in other cases vomiting is an early and constant symptom, or the patient complains of a persistent indigestion or heartburn or acid eructations. Asthenia, cachexia, and loss of weight are usual accompaniments. Pain and discomfort in the epigastrium are common, and when a tumor has been felt, the diagnosis of cancer can generally be made. The condition of the appetite is as varied as the other symptoms; with some there is little interference with the desire for food, while in others the appetite is early lost.

I have just stated that when a tumor is associated with some or all of the symptoms enumerated a diagnosis of cancer can generally be made, but there are none of us who continually see these cases, whether it be in our own practice or in those of others, who do not have it brought home sooner or later by having some patient on whom we have placed a label of incurability get well, that our conclusions after all may be based upon defective observations and reasonings. I learned of such a case recently. There had been in a patient over fifty years of age just such typical symptoms; a consultation was held and the consultants concurred in the opinion of the attendant that the disease was cancer. The unfortunate sufferer, face to face with his doom, determined to do one thing for himself—take a sufficient amount of saleratus to relieve the acidity, which had made life almost unbearable. Beginning with very large quantities, which he reduced with lessening acidity, he slowly improved till he fully regained his weight and strength.

Nearly two years ago a business man came to my office for examination. Several symptoms, together with a tumor in the region of the stomach, were strongly suggestive of carcinoma, and I was not surprised to hear him say that two other physicians had already given him that diagnosis, and one had urged an early operation. When I had completed the chemical as well as the physical examination, I had no hesitation in assuring him that he did not have a cancer; I have since had the satisfaction of seeing him make a full recovery. These two cases are cited to emphasize the unreliability of symptoms as a basis for diagnosis. I would not disparage their value, however, as corroborative indications.

The correct diagnosing of carcinoma of the stomach has been a problem to which scientific effort of the brightest minds in gastroenterological work has been directed. If we compare the knowledge of twenty-five years ago with that of to-day and realize that the following diagnostic aids were then unknown, we must conclude that real progress in scientific diagnosis is largely confined to this later period. During this time it has been learned how to inflate the organ so that not only the size and position of the viscus can be accurately outlined, but it can be clearly shown whether tumors, which seem to be connected with the stomach, are united to, or separate from it. A reliable determination of the motor powers of

*Read before the Connecticut State Medical Society Meeting at Hartford May 24, 1905.

the organ is now possible. It is almost unnecessary to add that the chemical analysis of the stomach contents is one of these latter day methods.

The life of a gastric carcinoma may be divided into three periods: (1) from inception to the appearance of an exudate; (2) from the beginning of the exudate to the breaking down of the neoplasm; (3) from the breaking down of the neoplasm to death.

Of the first period we can say but little. The patient suffers no inconvenience to send him to a physician; hence the doctor has had no opportunity of working to discover any indications which may exist that would point to a cancer. We have reason to believe that the length of this period differs greatly in different cases, as cancer of the stomach partakes of the same general characteristics of cancer in any other part of the body. We know a slowly developing warty growth may persist for years; or without any discoverable cause take on at any time a rapid proliferation which, if not interfered with, soon ends in death.

Our diagnostic investigations are confined to the second period, and the sooner the telltale exudate is discovered the more hope there is of saving the life of the patient. If discovered early, before surrounding tissues and organs have been invaded, the surgeon has his opportunity If the discovery is made late, there is no hope. Whatever methods may be advanced for discovery of cancer prior to the period indicated, which is also the beginning of symptoms, are entirely impracticable and have no place in the present paper.

In a recent issue of *Progressive Medicine* appears a presentation of four tests, all advanced during the last two years; and again in the same publication is an article on "The Chemical Significance of 'Occult' Blood in Gastric Disease." By way of explanation this article defines occult blood as such small quantities of blood in the stool that it cannot be seen macroscopically, and the author states further that "the physical condition of blood is usually so altered by its passage through the intestine that it is not easily recognized by the microscope, hence the need of a delicate chemical test which Boas has elaborated from that suggested by Weber."

Boas, Hartmann, Joachim, Schmilinsky, and Schloss have all contributed something to the present fund of knowledge which is epitomized as follows: (1) "Occult blood in feces or stomach contents is of the same significance as macroscopic hemorrhage, and of the same value in diagnosis; the advantage of the test is that by its use a much smaller quantity of blood can be detected. (2) Occult blood is constantly found in cancer of the gastrointestinal tract. (3) It is present intermittently in ulcer. (4) It is occasionally present in organic and spastic pyloric stenosis. (5) It is absent in acid, anacid, and subacid gastritis, hyperacidity, hypersecretion, and neurosis."

The technique of the test is as follows: "The patient must be kept on a diet free from all sorts of meat, cooked and uncooked, for several days; this includes even fish. The stools must be made soft by some mild laxatives, such as Carlsbad salts. A small quantity of feces, two or three grains, is thoroughly mixed with 20 c.c. of water. This is first extracted with 20 c.c. of ether to remove the fats, etc., from the stool. This is a very necessary part of the procedure, otherwise the ethereal extract becomes a thick emulsion with which it is impossible to get accurate results. This mixture is extracted with one-third its volume of acetic acid and thoroughly shaken; 10 c.c. of ether is then added and the mixture is again thoroughly shaken. After a short time the ether will rise to the top. If this does not occur quickly a few drops of absolute alcohol will hasten the separation of the ether. To 2 c.c. of the ethereal extract is then added 10 drops of freshly made tincture of guaiac (resin of guaiac 1, absolute alcohol 25), with 10 to 20 drops of an old ozonized oil of turpentine. No water must get into the mixture, and the oil of turpentine must be added slowly drop by drop. If blood is present in a few seconds an intense blue color will appear in the mixture, which gradually assumes a reddish-violet tint. A solution of hydrogen peroxide, if used in the same proportion as the oil of turpentine, if free from impurities, will give almost equally prompt results."

I desire to call your attention to the four tests already alluded to. These tests are: 1. The tryptophan reaction; 2. Salomon's albumin test; 3. Gluzinski's test; 4. The estimation of the fatty acids in the urine. The tryptophan reaction has been found in some cases unreliable—Salomon's test for albumin is of considerable diagnostic value. It is made in the following way: The patient takes only liquid nourishment for twenty-four hours, and then at noon he takes his last liquid meal, free from any albuminous food; at 8 o'clock in the evening the stomach is very carefully washed with water. The next morning the stomach is washed with a pint of physiological salt solution. The same fluid is run in and out several times. This water is then tested for albumin by Esbach's test and for nitrogen by Kjeldahl's method. It is believed that when a distinct reaction is obtained and albumin found to be present it is always in favor of carcinoma.

"Gluzinski's test is based on the fact that a chronic mucous gastritis develops on the basis of an acid gastric catarrh during the transition of an ulcer into a cancer. If, then, we can exclude the healing of the ulcer, we have a valuable test for the development of a cancer in an ulcer. The healing of an ulcer never gives rise to a mucous catarrh. The stomach is tested three times the same day—first rinsing it out fasting in the early morning, then three-quarters of an hour after a test breakfast, and finally, four hours after a beefsteak test meal. When there is absent or very slight HCl in one of the tests while after the other meals there is strong HCl reaction, and if at the same time the long bacilli are present (though this is not indispensable), then the indications are strongly that the acid catarrh is beginning to change into a mucous catarrh and that a cancer has begun to develop in the floor of the ulcer. The fourth method is based upon the estimation of the volatile fatty acids in the urine in cases of suspected carcinoma."

The discovery of the bacillus was the cause of increased microscopic study of the stomach contents some few years ago. The investigations of Schlesinger and Kaufman settled that the bacillus and lactic acid were present at the same time, and each has about the same diagnostic value. Samberg has recently experimented with these bacilli and has isolated two varieties, the long and the short. The concentration of lactic acid destroys all the bacteria save the long variety, hence we readily see why in cancer of the stomach large quantities of these organisms are present.

Kaufman and Schlesinger have shown that these long bacilli are completely destroyed by HCl; but others developed and multiplied rapidly in the culture medium made with organic (lactic) acid.

It is a well established fact that no one isolated symptom or condition can be considered pathognomonic of carcinoma of the stomach. Free HCl may be absent or present. No diagnostician to-day would consider that alone of any importance. Lactic acid may be found, but because Uffelmann's test is positive it does not necessarily follow that the disease is cancer.

I believe, however, when the two conditions (free HCl absent and lactic acid present) are coexistent in the same stomach, even though there is but a trace of lactic acid, we have strong ground to suspect a carcinoma. If there is inability to digest albuminous food at the same time, we have the three legs to our diagnostic stool and a diagnosis may be made, whether a tumor be felt or not. If, then, the symptoms point to the same conclusion we may have the greater assurance. If there are no other symptoms these will be sufficient to make a diagnosis. It is always better to let a diagnosis be made from several, rather than one examination. This holds good especially in the chemical examination of the stomach contents. To emphasize some of these points we can make an application to certain special cases. If there be stenosis of the pylorus due to a cicatrix from a former ulcer we will find something like the following symptoms; cachexia, emaciation, ectasy, a decided tumor, and quite likely hematemesis. These are very suggestive of carcinoma, but the examination of the stomach contents reveals a large amount of free hydrochloric acid and no lactic acid. It is in this class of cases we need to make an examination every week to ascertain if there is any change in these constituents of the stomach contents; the whole matter will hinge on this very point, and if there is no substantial change the diagnosis is pyloric stenosis, but of a benign nature. If there is progressive decrease in the HCl and development of lactic acid, with weakened albumin digestion, it is carcinoma. A reliable diagnosis can never be made from one symptom.

It is frequently difficult and sometimes impossible to diagnose between carcinoma and atrophic gastritis without having the patient under observation a long time. If the patient emaciates rapidly, and other symptoms likewise grow much worse, it is carcinoma. If the conditions show little decided change it is gastritis.

It is always advisable to locate the tumor if possible, but in most cases of cancer the tumor can be palpated. In cases where there is doubt and there is objection to anesthesia, place the patient in the dorsal position, with head toward a window, where there is good light; draw the shade so that a modified light falls upon the abdomen; watch the peristaltic wave pass over the position where a possible tumor may be located; if the movement at this point is lessened or lost it indicates a tumor. Patients may be palpated in a warm bath when tumors can be more readily felt. The question of age must not be allowed too much weight in our diagnosis, for while cancer of the stomach is more frequent in middle life and old age, it may occur at any time. The differential diagnosis between cancer and tuberculosis of the peritoneum in young persons can be decided without difficulty by a chemical examination of the stomach's contents.

Carcinoma in nearby organs may be difficult to diagnose from that of the stomach. Usually in such cases we will be helped by inflation of the stomach.

The differential diagnosis between carcinoma and ulcer is not difficult, even though some symptoms seem conflicting. The history of the case; a study of the whole symptom-complex of the disease, and a chemical examination of the stomach contents will make the matter plain.

Finally, while I have endeavored to present the chief difficulties in diganosing carcinoma of the stomach and approved methods of meeting the same, I am not insensible to the fact that no two cases are exactly alike, and that any one of us may meet in our next case conditions which will try all our knowledge, and give us something new to record concerning carcinoma of the stomach.

---

## A REPORT OF THE WHITMAN METHOD OF TREATMENT OF FRACTURE OF THE NECK OF THE FEMUR.*

By F. E. ASCHCROFT, MD.,

DEADWOOD, SOUTH DAKOTA.

THE object of this paper is to call your attention to a method of treatment of fracture of the neck of the femur advocated by Dr. Royal Whitman of New York in the MEDICAL RECORD, March 19, 1904, and to demonstrate, in the person of a patient, a good result in the only case in which we have had an opportunity to test it.

The disabling results of this accident are sufficiently familiar. In fact, according to published statistics, complete restoration of function is almost never attained, and in the large majority of cases the patients are practically crippled for life. Dr. Whitman, who has repeatedly called attention to the frequency of the accident in the young, as well as in the aged, thinks that these results may be accounted for, at least in part, by ineffective treatment, the fragments either not being in contact, or not being properly supported during the period of repair. He suggests that the shortenings should first be overcome by direct traction on the limb, which should then be carried to the limit of normal abduction, or about forty-five degrees from the line of the body. In this attitude the trochanter is in contact with the side of the pelvis, so that upward displacement is impossible, while the tension on the capsule should remove folds, and should direct the fragments towards one another.

The abductor muscles are relaxed and the direction of the iliopsoas is so changed that muscular contraction can no longer exert a harmful influence. The author truly says that "a new treatment must appeal to reason, rather than to experience." This method appealed to our reason more forcibly because of the disappointing results that have usually followed better-known methods.

April 18, 1904, I was visiting at a mining camp eight miles from here, and was informed that I was wanted at the boarding house, a man having been hurt in the mine. I hurried there and found Mr. J. C., age 42, height 5 feet 10 inches, weight about 190 pounds, lying on a bed, with his right foot inverted to a right angle. He at once demanded of me something to relieve his continuous intense pain, and would not permit me to approach him for any other purpose than to administer morphine hypodermically. Pending the arrival of Dr. Bowman, who had been telephoned for, he allowed me to repair a scalp wound of considerable size, and minor injuries to the hands and arm. I elicited the following account of the accident: While the man was in a crouching or stooping position, preparing to pick up a rock, weighing about fifty pounds, from the floor of

* Read before the South Dakota State Medical Association, July 6, 1905.

the stope in the mine in which he was working, a mass of rock of about two tons' weight fell from the roof, struck him on the back, shoulders, and head, crushing him to the floor. He felt a sudden snap in his right hip and continuous pain from that time. After a few minutes he was extricated and carried to where I found him. When Dr. Bowman arrived we anesthetized the patient and made a diagnosis of intracapsular fracture of the neck of right femur, and contusions and lacerations of the knee and leg. We prepared him for removal to Deadwood by train. When he had recovered from the chloroform we informed him that he had a broken hip, and would probably be a cripple the rest of his life; that we would do our best for him, and he must not hope for anything better than a leg shorter than the other, some pain, and a limp as long as he lived.

At St. Joseph's Hospital we applied treatment as outlined by Dr. Whitman, except that we did not

Röntgen picture showing the result of treatment. The arrows point to the line of fracture.

anesthetize the patient. I will describe, in the author's own words, the application of the method: "A piece of ordinary seamless shirting, such as is used for plaster jackets, about six feet in length, cut and sewed in shape to cover the body and limb, is first applied and fixed securely in place by bands passing over the shoulders. This is threaded with several long bandages, the 'scratchers,' designed to keep the skin in good condition. It is also advisable to insert a substantial 'dinner-pad.' The patient is then anesthetized and is placed in a position for the application of the bandage. The head and shoulders may be conveniently supported on a box of proper length and about eight inches in height; the pelvis rests upon a sacral support. A wide, firm band of cloth is then carried about the perineum, the two ends of which, united over the shoulder and held by an assistant, furnish counter traction. If the fracture is complete, the shortening is first entirely overcome by the traction and counter traction. The limb, in the extended attitude, under traction is slowly abducted by the assistant until the trochanter is fairly opposed to the side of the pelvis; the operator meanwhile pressing the trochanter downward and inward. In some instances there is a distinct snap as the outer part of the neck slips beneath the rim of the acetabulum, and in any event the abduction is increased until the trochanter is firmly apposed to the side of the pelvis. The primary object of the abduction is by leverage against the upper border of the acetabulum to overcome the deformity; secondly, by tension on the capsule to remove folds, to appose the fragments, and by actual contact of bone with bone to oppose redisplacement.

"A plaster spica bandage is then applied in the usual manner from the mammary line to the toes; this should fit snugly about the hip, and, most important of all, should completely enclose and support the buttock. As a rule the support is comfortable because it is efficient. It absolutely prevents rotation of the limb. The support may, at the end of four weeks, be shortened, to allow action at the knee, and at the end of eight weeks, or when it may appear that union is assured, it may be removed. The best time for the application of the treatment is immediately after the injury, for with the comprehensive support of the whole limb, from the toes up, there is little danger of constriction."

In the case of our own patient there was so little pain that he jokingly said we were deceiving him and did not believe a bone was broken. The period in bed was free from event, except that on the eighth day the cast was broken at the groin by lifting on the heel during an attempt to roll him over in bed to place a bedpan.

On the tenth day the cast was removed and replaced by a new one, without anesthesia. At the expiration of eight weeks the patient was allowed to cut his own cast, emerge from his shell, and move about on crutches, and after a few weeks he discarded these for a stout cane. He now, fourteen months after the injury, walks without a cane or any support whatever, with a scarcely perceptible limp, and has only a slight pain at the knee. He thinks his injured leg is half an inch longer than the other, but the difference is so slight that it is difficult to demonstrate which is the longer. At the hip there is some limitation of motion in all directions, which is gradually diminishing, and may ultimately not be apparent. He has returned to his work as a miner in the same mine where he sustained his injury, and is considered an ablebodied man, and receives full pay. pay.

This *x*-ray picture, taken thirteen months from the accident, illustrates what we call a good result. If I can induce a few to reread Dr. Whitman's very lucid article, I am repaid.

---

**Empyema.**—James Berry says that thoracotomy for this condition should always be done under as light anesthesia as possible, and the patient should never be turned on the sound side. The patient is kept flat on the back, and is drawn so far over the edge of the table that the operator, seated on a low stool, can make the incision as far posteriorly as desirable. Omission to draw the patient sufficiently far over the edge of the table accounts for many of the cases of relapsed empyema. Various forms of tube have been recommended, but the simplest is the best. Nothing is really better than the common T-shaped tube made of two large pieces of stout india rubber tubing. In the middle of the shorter tube two holes are cut on opposite sides, and through these the longer piece of tubing is drawn. The short or horizontal limb of the T prevents the tube from slipping back into the pleural cavity. It is scarcely necessary to point out that this unpleasant accident should be avoided. It is more easy to lose a tube in the thorax than to find it again, or to remove it when once it has disappeared from sight.—*Clinical Journal.*

## THE THERAPEUTIC USES OF SUNLIGHT.

PHYSICAL methods have come to occupy an important position in therapeutics, and perhaps the most notable development in this field during the last decade is concerned with the application of light for the cure of a variety of pathological processes. It is really important that the physician keep in touch with the advances in this field, for some of them have already been exploited, and it must be admitted with considerable success, by the nature healers and other irregular practitioners. Various sources of light have been employed, but it has been found that sunlight is the most intense of all. Its efficiency is affected, however, by the state of the atmosphere, particularly by its humidity, for the latter greatly retards the chemical rays, though it has little effect on those of a thermal nature. It is quite evident, therefore, that a high altitude and a clear, dry climate constitute very important factors in the application of heliotherapy.

The beneficial effects of sunlight have been known to the peoples of the earth from very early times, and we find repeated references to its use in the writings of the old Greek physicians. The subject was again rejuvenated during the last century and has received considerable scientific attention more recently. The favorable effects of general sun-baths may be traced to the factors of increased perspiration, with a corresponding increase in the excretion of deleterious substances; a prolonged hyperemia of the skin, resulting in a derivation of the blood from the internal organs to the surface of the body; a stimulation of the metabolic processes; a direct and peculiar action on the blood and the vessels; and finally a bactericidal effect in the superficial layers of the skin. The indications for the use of sun-baths may be found in diseases of metabolism (diabetes, gout, etc.), in congestions in the internal organs (cardiac defects, asthma), and in anemia, chlorosis, general weakness or protracted convalescence, skin diseases, scrofula, and rickets.

The modern system of local light therapy owes its development largely to the efforts of the late Prof. Finsen of Copenhagen. He based his theories of treatment on the bactericidal properties of sunlight, but later also employed the rays from an electric arc, as being more convenient. The splendid results he obtained in lupus and other parasitic dermatoses are well known. The extension of the method to other surgical affections has been greatly developed by Bernhard of Switzerland, who has also been favored with very satisfactory results. In a recent contribution to the *Zeitschrift für diätetische und physikalische Therapie*, August, 1905, he describes his observations made at a sanatorium in the Engadin, at an elevation of over 5,000 feet, with a southerly exposure. This location was favorable not only because the rare atmosphere allowed the chemical rays full play, but also because the general temperature was low enough to permit sun-bathing without any discomfort being produced by the heat. Bernhard reports successful cures in lupus from exposure during a considerable period to the rays of the sun alone without the use of any accessories. Furuncles, phlegmonous processes, and all streptococcus infections were greatly improved, and the results in tuberculosis of the superficial glands and joints were very favorable. In addition to bactericidal powers, the sun's rays also possess other therapeutic properties. Epithelial formation is visibly promoted by exposure to the sunlight and flabby granulations are stimulated to renewed and healthy growth. The same author, in another paper, in the *Zeitschrift für Chirurgie*, July, 1905, also notes the favorable action of sunlight in cases where a transplantation of skin flaps has been performed, the adhesion of the flaps and their final attachment being markedly hastened.

The suggestions contained in these are interesting and timely, and among other things may exert an influence upon our present methods of wound treatment. Occlusive dressings have been quite universally employed for both primary and secondary wounds, although there is apparently no reason why, after the danger of infection is once past, factors with such well marked healing tendencies as have been proved to be associated with sunlight and fresh air, should be entirely excluded. Sunlight is an agency which is easily obtained and readily applied and as a therapeutic factor in surgical procedures, it is deserving of more extended attention and study.

## THE PURIFICATION OF WATER SUPPLIES BY COPPER.

ABOUT two years ago there was issued by one of the bureaus of the Department of Agriculture, a publication dealing with this question, in which it was recommended that the object be accomplished by the use of the salts of copper. Moore and Kellerman, the authors of this method, claimed that the addition of minute quantities of copper to the water at ordinary temperatures, resulted in the destruction not only of the common green algæ, but also of the pathogenic bacteria. A similar result could also be accomplished, it was claimed, by the suspension in the water of a quantity of copper foil, from which was given off sufficient of the metal to produce a colloidal solution.

The daily and scientific press has discussed these observations pro and con, but nevertheless the question is still sub judice and more conclusive scientific proofs of the value of the method must be gathered together, before it can either be entirely condemned or adopted. Among the more recent investigations is one by a foreign observer, whose conclusions are of considerable interest. Major C. E. P. Fowler (*Journal of the Royal Army Medical Corps*, September, 1905), has subjected the method to a practical test, using in his experiments, *Bacillus coli communis*, for seeding the water, because its resistant power is slightly

greater than that of *Bacillus typhosus*, and it may readily be recovered from the water, even if present in very minute quantity. Specimens of the ordinary London tap water, and also some drawn from the Thames were employed. These experiments were very carefully carried out, and Fowler concludes that a contaminated water, standing for 20 hours in a copper vessel, even though a large quantity of copper foil be suspended in it, is not rendered safe for consumption, by this treatment. Copper sulphate was found to act as a fairly efficient germicide for intestinal organisms in 24 hours in clear water containing about one part to 60,000 parts of fluid, or in turbid water containing one part to 30,000.

If an individual drank one quart of this weaker solution per diem, he would be taking about ¼ grain of the copper sulphate, of which the usual astringent dose is from ½ to 2 grains. If long continued, this would probably harm the consumer of the water. The author has shown by his investigations that although the findings in the laboratory might prove correct and afford great promise, they would most likely break down in a practical application of the method. The procedure as originally advocated need not, however, be condemned, for it has been found of service in freeing a reservoir from the obnoxious growth of green algæ, and for this purpose a much weaker dilution of copper sulphate is effective than is necessary to destroy pathogenic bacteria.

## THE FATTY CONSTITUENTS OF INFANTS' MILK.

Wasting in children, as in adults, must be due to deficiency in quantity or quality of food, enfeeblement of the digestive processes, or general disease. In infants by far the most common cause is some defect in the nourishment supplied, with resultant gastrointestinal derangement. Breast-fed children, therefore, suffer less commonly than hand-fed children, although the former by no means invariably escape. Often the untoward result is averted by timely and intelligent milk-modification. When, however, well-developed marasmus has been set up, none of the usual measures appears to be of much avail. One of the causes for this relation of events that in the past seems to have been too much neglected, is dwelt upon at some length by Dr. Heinrich Stern (*Archives of Pediatrics*, June, 1905), who dilates upon the importance in this connection of the chemical character of the fatty substances contained in milk. As he points out, the presence for protracted periods in mother's milk of fat in abnormal amount or imperfect emulsion or in perverse combination, will eventually give rise to gastrointestinal disturbances with metabolic irregularities and toxic phenomena, terminating in bodily decline and atrophy. Such a condition, if permitted to continue for a considerable period, cannot always be checked in time to avert a fatal termination, even if meanwhile the secretion of the fatty principles of the mother's milk has been restored to normal.

The problem is still more difficult in the case of cow's milk, because we have here a difference in the composition of the fat as compared with mother's milk. The former contains less fat, has a lower specific gravity, a somewhat higher melting-point, and a considerably higher solidifying-point. Cow's milk, further, contains a much larger proportion of volatile fatty acids, the most important of which is butyric acid, the mother-substance of the acetone bodies. These acids are decided irritants to the gastrointestinal mucous membrane of the infant. Besides, the fats of mother's milk are more readily digested and assimilated by the infant than are those of cow's milk. As a substitute for milk-fat whenever this proves a source of disturbance, Stern proposes the use of yolk of fresh hens' eggs, which is well borne and well liked as a rule, is readily absorbed, yields little or no volatile fatty acids, contains large amounts of lecithin, and a diastatic ferment that aids in the conversion of amyloid substances, and stimulates the digestive secretions. In order to obtain good results, the yolk-fat should completely replace the milk-fat and the amount, without being excessive, should be adequate, that is in conformity with the caloric and nutritive demands of the organism. A quarter teaspoonful of yolk will at first be sufficient for each feeding, and the amount may be increased as need arises. The yolk may advantageously be admixed with skim milk, which may be further modified in accordance with the requirements of the individual case. It is believed that the electric conductivity of such a mixture is somewhat greater than that of native cow's milk.

## The Jewish Physician in History.

It is probable that no other race has been influenced in its development and general progress by members of the medical profession to so great an extent as has been the case with the Jews. In the earliest times the practice of the healing art was stamped with prestige and authority since it lay largely in the hands of the Levites, and therefore acquired some of the distinction belonging to the priestly order. The functions of the members of this tribe, especially in assisting at the sacrificial ceremonial, no doubt rendered it especially easy for them to obtain an insight into the workings and functions of the organs of the animal body, thereby becoming possessed of knowledge that could readily be applied to the treatment of disease in man. How intimately at that time the care of the body was associated with the rules of religious observance is evident from the many regulations regarding public and personal hygiene laid down in the Mosaic laws, sanitary doctrines that in principle are most of them as sound to-day as then. Somewhat later on in the evolution of the race it appears that the practice of medicine became largely an avocation among the expounders of the laws, as these functionaries for a long time received no remuneration for their services in legal matters and so took up the other learned profession as means of livelihood. During the later periods of disaster and captivity, and the centuries of dispersal and persecution, the Jewish physicians assumed a conspicuous position in striving for the rights of their race, in assisting their less fortunate fellows, and in influencing rulers to mitigate the hardships to which the Jews were universally subjected. Many of them became the court physicians and favorites of powerful monarchs, some even enjoyed the confidence of Popes and prominent ecclesiastical functionaries, others advanced the cause of their people by writings of a literary or controversial nature. An interesting survey of these

members of our profession is to be obtained from a little work entitled "Jüdische Aerzte und ihr Einfluss auf das Judentum," which has just been issued by Dr. Simon Scherbel. One of the most prominent of the earlier personages mentioned is Chasdaï, who became a minister under the Calif Abdul-Rahman III and did much to establish the position of the Jews among the Moslems in Spain during the tenth century, as well as to foster the study of the Talmud in that country. Jehuda Halevi, who lived a hundred years later, was a busy physician who was also the author of distinguished practical and philosophical works. The great Maimonides of Cordova is included among the list of physicians by the author, who says that he created what is almost a new Talmud, and alleges that Richard Cœur de Lion wished to make him his court physician, in spite of the edicts of the Popes Eugenius, Nicholas, and Calixtus that Christians should not employ Jewish physicians. In Spain for many years they were practically the only practitioners of medicine. Somewhat later the notorious Pope Alexander VI had as personal physician a Jew, Bonet de Lates, who subsequently became attached to the court of Leo X. The edict against Jewish physicians was finally raised by Sixtus V, largely at the instigation of two then celebrated physicians, David de Pomis and Elia Montalto. In the latter part of the eighteenth century Mendelssohn's efforts in behalf of his compatriots were ably seconded by his friend the physician Marcus Herz, who contributed much toward the elevation of the Jews of Germany. In still more recent times Ascher, Steinheim, Erter and Johann Jacoby have been prominent, and the author closes his enumeration with the widely known names of Strassmann, Neumann, Baginsky, and Senator.

### Child Suicide in Germany.

The yearly increase in the number of child suicides in Germany has given rise to much discussion as to the causes of this unhappy state of affairs. During the past eighteen years 747 suicides of children have been reported, but the annual proportion has been rapidly growing. For example, in 1902 seven cases of child suicide occurred in Saxony, but in 1903 the number of persons under fourteen years of age who killed themselves had risen to twenty-one. The suicides of adults during the same period increased only from 1,388 to 1,427. Various suppositions have been advanced to account for this morbid tendency among the young. The socialists consider it the result of the generally increased difficulty in making a livelihood which darkens the lives of children as well as those of their parents. The clergy maintain that the growth of irreligion is to blame, and that a revival of spiritual aims would be followed by greater serenity and love of life. Finally, critics of the school system assert, and this seems to us the most rational view, that the children are forced too much, that they are compelled to attempt work which is impossible for those whose capacity is at all below the average, and that the fear of punishment and of falling behind their comrades urges the less intelligent to seek relief in self-destruction.

### Euthanasia.

The question of purposely ending the life of individuals suffering from incurable disease or hopelessly injured in railway or other disasters was brought before the American Humane Association at a recent meeting in Philadelphia by several advocates of this practice who endeavored to have the society stamp it with the seal of its approval. The chairman, however, ruled out the proposition after some argument, on the ground that the articles of incorporation of the society confined its operations to cases of cruelty to animals or children. The question is one that has often been raised by would-be philanthropists, and in 1895 the question whether physicians ever have the right to terminate life was one of the subjects of discussion at a Medicolegal Congress held in this city under the auspices of the New York Medicolegal Society. The views of the medical profession are well expressed in the classical reply of Larrey to Napoleon in the pest house at Joppa. When the emperor suggested to the great surgeon that it might be an act of mercy to put an end to the illness of some of his wretched patients, the answer was, "Sire, it is my function to preserve life, not to destroy it."

## News of the Week.

**Medical Union Assured.**—As is noted in another column, the reunion of the long divided medical profession in this State is now assured. The vote by which the New York State Medical Association decided the question of union was the very decisive one of 1517 to 2. This very nearly met Dr. Goffe's expressed desire that the vote might be unanimous.

**Anniversary Meeting of the Academy.**—On Thursday evening, November 2, the anniversary meeting of the Academy of Medicine will be held in Hosack Hall. The orator of the evening will be Dr. Arpad G. Gerster. The subject of his discourse will be hospital management. The anniversary meetings of the Academy are open to the public, and a large attendance is expected. A reception will be held after the delivery of the oration.

**City's Tuberculosis Sanatorium.**—The plans have been completed for the New York City Sanatorium for Consumptives, which it is purposed to erect near Castleton on the highest point of Staten Island. This location was chosen on account of the prejudice among the poorer classes against leaving the city for treatment. The plans provide for eight buildings for patients, with a capacity of 100 beds each, an administration building, kitchen and dining halls, and a power house. The architect estimates the expense at $2,000,000, which is less than $3,000 per bed. The ward buildings are arranged in a semicircle about the administration buildings, and all of the local advantages of position have been taken advantage of in providing sunshine and free circulation of air for each building.

**A Pan-American Quarantine System.**—At the meeting of the International Sanitary Convention held in Washington, D. C., on October 13, the delegates accepted the forty-nine articles of the Paris Convention of December 3, 1903, with only a few modifications required by the conditions in tropical countries. When ratified by the different South and North American governments there will be on practically all of the American continent one system of quarantine and preventive measures. About thirty delegates were in attendance when the convention was opened on October 9, representing nearly every South American republic and the West Indies. Secretary of State Root, Assistant Secretary Horace A. Taylor of the Treasury, and Surgeon-General Wyman of the United States Marine Hospital Service, delivered the opening addresses.

**Nothnagel's Last Words.**—The *Deutsche medizinische Wochenschrift* in its issue of September 28 contains a reproduction of the manuscript notes found at Nothnagel's bedside after his death. These were written after several attacks of angina pectoris,

and evidently with the sense of impending death. Translated they run as follows: "Attacks of angina pectoris with extremely severe pain. Pulse during the attack very variable, at one time slow, about 56-60, quite regular, marked tension; then again rapid, 80-90, quite regular in force and rate, finally complete arrhythmia, very unequal, sometimes rapid sometimes slower, with variable tension. The first warnings of these attacks date back several (3 or 4) years, at first very slight, gradually more and more pronounced. Real attacks with great pain began only five or six days ago. Written on July 6, 1905, late at night, just after I have had three severe attacks."

**Impure Olive Oil.**—The chemist of the San Francisco Board of Health has made an examination of many specimens of olive oil bought in the open market, and finds that most of those found to be impure bear foreign labels. About one in four specimens labeled as imported from Italy or France was found to contain cotton-seed or sesame oil. Of seventy-two samples of California oil, however, only five were found to contain impurities. These facts are believed to demonstrate, not so much the impurity of imported oils as that the dealers in adulterated goods protect themselves by the use of apparently foreign labels. A list of many dealers in adulterated oils is published in the report.

**Disposal by Will of Corpse.**—In compliance with a provision of the will of George William Catt, president of the Atlantic, Gulf and Pacific Company, and a well known civil engineer, who died last week in his home at Fifty-seventh street and Seventh avenue, his body, after a funeral service had been held over it, was given without restriction to the Bellevue Hospital Medical College to be used in the interests of science. Such disposition of the testator's corpse is authorized by section 305 of the Penal Code of the State of New York, which reads: "A person has the right to direct the manner in which his body shall be disposed of after his death; and also to direct the manner in which any part of his body, which becomes separated therefrom during his lifetime, shall be disposed of; and the provisions of this chapter do not apply to any case where a person has given directions for the disposal of his body or any part thereof inconsistent with those provisions."

**Harvey Society Lectures.**—The following are the titles of the lectures to be given this winter under the auspices of the Harvey Society: November 4, Prof. F. G. Novy, Trypanosomes; November 18, Dr. P. A. Levene, Autolysis; January 20, Prof. W. H. Park, A Critical Study of Serum Therapy; January 27, Prof. Lewellys F. Barker, The Neurones; February 2, Prof. F. S. Lee, Fatigue; February 9, Prof. L. B. Mendel, The Formation of Uric Acid; February 16, Prof. T. H. Morgan, The Extent and Limitations of the Power to Regenerate in Man and Other Vertebrates; February 23, Prof. Charles S. Minot, On the Nature and Cause of Old Age; March 2, Prof. J. C. Webster, Modern Views Regarding Placentation; March 9, Prof. Theobald Smith, Some Phases of Tuberculosis; March 16, Prof. W. H. Howell, The Cause of the Heart Beat. The first lecture by Prof. Hans Meyer on the Theory of Narcosis was delivered on October 7, and the second by Prof. Carl von Noorden on Modern Problems of Metabolism on October 14.

**Insanity Among Negroes.**—The annual report of Dr. W. F. Drewery, superintendent of the Central State Hospital, at Petersburg, Va., contains interesting statistics regarding the alarming increase of insanity among the negro population. The number of patients sent to the hospital during the year was 170 more than the previous year, showing an increase of about 50 per cent. The number in the hospital was 1,449, or 115 greater than the year before. The smallest number under care at any one time was 1,101 and the largest 1,305. The number present at the end of the year was 1,181, or 80 over the previous year. The growing prevalence of mental disease among the negroes is ascribed to physical conditions and degeneracy induced by indolent, unhygienic, and immoral methods of life, as well as to the influence of heredity, rather than to any forms of mental stress or overwork.

**The Terror by Night.**—According to the *Medical Press* the inhabitants of Liverpool were very indignant when an advertisement was circulated by the School of Tropical Medicine, offering a half-penny apiece for five hundred uninjured specimens of *Cimex lectularius*. It was not aversion to the experimental methods of the school, or tender-heartedness for the welfare of living creatures that aroused the storm, but the slur cast on the character of the town. It was freely alleged that the experimenters would be disappointed, as there was no more probability of five hundred bugs being found in Liverpool than of five just men being found in Sodom. Alas for the pride of the great cotton city! More than the desired number were forthcoming in a day, and since then the authorities have been simply overwhelmed with would-be caterers of the required insect.

**Yellow Fever in New Orleans.**—With the advent of cool weather a great improvement is being noted in the yellow fever situation. On October 15 for the first time since the beginning of the epidemic the number of new cases was below ten, only eight being reported. During the five days previously only eighty-four cases were reported, as against 108 for the preceding five days and 122 for the five days before that. Reports from the surrounding country are also very favorable and show few new cases.

**Cholera.**—During the period from October 5 to October 11, forty-seven cases of cholera, twenty-four of them resulting fatally, were reported from Poland.

**Yellow Fever at Panama.**—It is reported that yellow fever has been virtually stamped out on the Isthmus. During the first two weeks in October there was but one case, a non-employee, who was taken ill on September 29. The quarantine at Punta Arenas, Panama, Port Limon, and Colon has been raised, and it appears that the work of sanitation is progressing in a very encouraging manner.

**Ambulance Collision.**—At Brooklyn's hebdomadal ambulance accident on October 15 a St. John's Hospital ambulance taking an injured child to the hospital was struck by a Marcy avenue car at Bergen street and Classon avenue. The surgeon, Dr. White, escaped injury by jumping.

**Smaller Medical Classes.**—The registration just closing in the Cornell University Medical College shows a decrease over the best of the previous years. The three advanced classes are somewhat larger than usual but the first year class, which hitherto has contained an average of about 130 students, this year has less than 120.

**A Fireproof Library and Museum at Los Angeles.**—Through the generosity and public spirit of Dr. W. Jarvis Barlow, the Medical Department of the University of Southern California has established a museum and library in a fireproof building contiguous to the college hall. A circular letter has been sent by Dr. William A. Edwards, chairman of the committee in charge, asking physicians to contribute books, plates, charts, journals, rare and

curious instruments, and pathological specimens. It is hoped to make the collection of benefit to the entire profession of Southern California, and every effort will be made to make the library a complete source of reference.

**More Insurance Graft.**—The editor of a newspaper in a small town of Southern California recently published, under glaring headlines, an account of wholesale traffic in dead bodies by one of the great life insurance companies which are now attracting so much unsavory criticism. The statement was made that more than a thousand bodies had been bought in a single day and sold within a week at an enormous profit. It was the second issue of the paper and a decided "scoop." But, undoubtedly the ambitious editor mistook the word "bonds" for bodies and depended upon his inflamed imagination for the rest.

**Turbulent Undergraduates.**—The freshmen and sophomore students of the University and Bellevue Hospital Medical College at their annual rush recently displayed such vigor that a riot call was sent in to the East Twenty-second street police station. Every policeman on reserve and all who could be spared from nearby registration places were hustled around to quell the disturbance. They arrested three freshmen. A hundred freshmen and seventy-five sophomores, more or less, were engaged in the encounter, and as a result the senior students had two hours of practice at minor surgery and bandaging.

**Hospital Cashier Arrested.**—The cashier for the New York Polyclinic Medical School and Hospital, in East Thirty-fourth street, has been arrested on the charge of stealing about $4,500 from the hospital, the indictment containing three specific charges of forgery in the third degree.

**Washington Heights Hospital Dedicated.**—The new Washington Heights Hospital, which was informally opened on August 1, was formally dedicated on October 15. The hospital is using the old Hosea B. Perkins house at Broadway and 179th street until the new building is erected.

**Open Air Cure for Monkeys.**—Stimulated by the successful results of the open-air treatment of tuberculosis in man, the superintendent of the Lincoln Park Zoo in Chicago has decided to try the same plan with his thirty-eight simian charges. While it is true that most of the deaths among captive monkeys in this climate occur from tuberculosis, it is hardly likely that the abrupt transition from the superheated air of the animal house to the zero weather of the Michigan shore will prove as beneficial as it is hoped.

**New Sanatorium for Brooklyn.**—Application for a charter has been made to the State Board of Charities by the incorporators of the Long Island Open Air Sanatorium of Brooklyn, formed to furnish hygienic treatment for consumptives and to encourage work for the control of tuberculosis on Long Island.

**Obituary Notes.**—Dr. Max Urwitz of Houston, Texas, died of apoplexy on October 4, at the age of fifty-six years. He was born in Prussia but came to this country while a young man and was graduated from Tulane University in 1881. He remained for some time in New Orleans, but for the last eighteen years he practised in Houston.

Dr. Joseph B. Jones of Brooklyn, died on October 10 in his seventy-seventh year. He was born in New York, and, after graduating from the College of Physicians and Surgeons in 1855, moved to Brooklyn. He served several terms as coroner in the old city of Brooklyn, and once as health commissioner. He was long a member of the Board of Education, and in late years was attendance superintendent of the Board of Education. He was an ardent devotee of athletics, and for several years conducted a gymnasium in old Montague Hall.

Dr. Vernon G. Culpepper of Portsmouth, Va., is dead at Norfolk, Va., of paralysis, at the age of fifty-two years. He was graduated from the Medical Department of the University of Virginia in 1876.

Dr. Thomas Addison Jenkins of Brooklyn, died on October 11 of pulmonary tuberculosis at the age of thirty-three years. He contracted the disease six years ago while taking a post-graduate course in the Nursery and Children's Hospital, and vainly battled against it by a four years' residence in Denver, Col. He was a graduate of Princeton College and of Bellevue Medical College in the class of 1897.

Dr. Carl Seiler died at Easton, Pa., on October 10 at the age of fifty-six years. He was born in Switzerland, and was graduated from the Medical Department of the University of Pennsylvania in 1871. He practised his profession in Philadelphia for a number of years.

Dr. Eugene P. Bernardy of Philadelphia died at Atlantic City of uremia on October 11, at the age of fifty-eight years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1868. He served as demonstrator of surgery and of anatomy and later as instructor in medical jurisprudence and toxicology in the University. He was also for a time physician to the Philadelphia Dispensary, obstetrician to the Philadelphia Hospital, physician to the French Benevolent Society, and to the French Consulate. In 1899 he received the decoration of the palms of the French Academy, and only recently was appointed Belgian Consul at the port of Philadelphia.

Dr. Charles M. Shanely of Barataria, La., died on October 9 of yellow fever in consequence of his heroism in volunteering for service against the yellow fever epidemic while still weak from an attack of the disease, from which he had barely recovered. The work proved too much for him, and he suffered a fatal relapse. Dr. Shanely was thirty-six years old and a native of Ohio. He was graduated from the Baltimore Medical College in 1894.

Dr. W. H. Mansell of Cedartown, Ga., died on October 8. He was graduated from the Atlanta Medical College in 1875.

Dr. Ira Kinnison of Cleveland, O., died September 27 at the age of thirty-four years. He was graduated from the Starling Medical College in 1898.

Dr. W. F. Milligan of Wabasha, Minn., died at Chicago on October 1, after an operation for appendicitis performed twenty-four hours previously. He was thirty-five years of age and was graduated from the Medical College of Ohio in 1892.

Dr. R. S. Boles of Mansfield, Ohio, died on October 3, at the age of sixty-two years. He was graduated from the University of Wooster, Cleveland, O., in 1869.

Dr. J. H. Witherspoon of Lancaster, S. C., died on October 4, at an advanced age. He was graduated from the Medical College of the State of South Carolina in 1861 and served in the Confederate Army throughout the entire war.

Dr. John A. Ouchterlong of Louisville, Ky., died on October 9 at the age of sixty-seven years. He was graduated from the University of the City of New York in 1861. Dr. Ouchterlong was Professor of the Practice of Medicine in the University of Louisville, and was knighted several years ago by King Oscar of Sweden and by Pope Leo XIII.

# Correspondence.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

A SANATORIUM FOR THE POOR—THE UNEMPLOYED—"BILE BEANS"—DANGEROUS IMMIGRANTS—CORONERS' SOCIETY—INQUESTS—TYPHOID OUTBREAK.

LONDON, September 29, 1905.

An appeal headed by the Princess Christian has been issued for £50,000 to build a sanatorium for working class patients. The "friendly societies" cannot use their funds for building, but they can for the up-keep, and it is understood they will do so. The trade unions have promised to assist. So we may expect that the institution will be established. Reckoning the number of patients for which it is to provide, I find the estimated cost of the building works out at £250 per bed. This is less than most of the existing sanatoriums, but far too much to spend on bricks and mortar. The chalet system could be provided for less than half, but even that may well be too much. I am afraid the magnificent example of the King's Sanatorium will be emulated by architects and others, but it should be remembered that a model institution for well-to-do persons is not the sort that should be proposed for cattagers. There is a tendency to throw away money on costly buildings when a much more modest provision would suffice. It is seen in our hospitals, asylums, charitable homes, and even in poor-law institutions; and not only in the buildings, but in all the equipments. Only the other day Sir H. Burdett declared that the sooner the profession recognizes that it is wrong to bring up students with the idea that they cannot perform operations except in a marble hall costing £10,000, the better it will be for science and for all requiring their care and treatment.

The subject of the unemployed in view of the approach of winter is causing much uneasiness and giving rise to numerous suggestions—more or less practical, rather less than more. It seems early for distress to become prominent or for loafers to be taking advantage of the benevolent. But already I have seen men apparently healthy and well fed wheeling a barrel organ, three of them with one; and on mentioning this to a friend, was told he had met four and five, with a woman and child, engaged in this arduous work. We shall have to be careful to prevent imposture.

The act passed last session to deal with the subject is about to be put on its trial, but its provisions are not giving satisfaction. Already there is a cry that the act does not directly allocate public money for setting men to work, and some are advocating a special session of Parliament to provide funds for that purpose. Some of the local authorities are appointing distress committees under that act, and others are putting in hand as much cleaning and other necessary work earlier than usual in order to minimize the suffering from want of employment in their districts. Nevertheless, this is the time chosen by the central government to dismiss thousands of skilled workmen from the dockyards—an immense proportion of whom will be thrown on the rates, and all of whom will be additional competitors for any work going. Thus our rulers give with one hand and take away with the other—another example of what Kipling calls "England's awful way of doing business."

The fraudulent advertiser flourishes in so many departments of modern life that there seems scarcely sufficient cause for the surprise expressed at the exposure in a law court of the "Bile Beans" fraud. You know something of this, but possibly have not heard that its success depended on the expenditure of £300,000 in advertising—mostly in so-called society and religious periodicals. Advertising in such cases really seems a weak euphemism for bribery, and it is a blot on our boasted freedom of the press that high-class newspapers, from the big dailies down through the weeklies and monthlies, are open to receive and eager to obtain these bribes. Morality of the press! Faugh! Religious papers! Distributers of falsehoods! "Partakers of other men's sins."

The proprietors of "Bile Beans" brought an action in the Edinburgh Court of Session against a druggist to prevent him from applying the term to other than their own nostrum. These parties had previously tried their game with some "tonic pills" which did not take with the public, but in November, 1899, imagined that the name of bile beans would succeed, and since then the £300,000 expended on the press has resulted in the sale of many millions of pills. So great is the gullibility of the public that on the conclusion of the contract the drug firm which manufactured them had some 31,000,000 pills in stock.

The Port Medical Officer of Health reports the death of two children among 257 immigrants on a steamer arriving in the Thames, and declares that their quarters were in a filthy condition. Little if any attempt had been made to clean these quarters, and the atmosphere was unbearable. It is under similar conditions that thousands of aliens are dumped in the East End of London every month, and political partisans scream about the sacred right of asylum when their opponents propose to restrict the danger. The advance of cholera should warn them.

The Coroners' Society is considering a bill which has been drafted to relieve juries from the obligation of viewing the bodies. It is said that there are different opinions in the society. But it is generally admitted that in a case of crime the jury should see the body. It is said a coroner who excused his jury from the inspection could not be blamed in certain cases—say, virulent diphtheria. But it is not likely he would risk dismissal by the Lord Chancellor or even censure. No doubt he is the best judge as to the necessity, and perhaps a bill merely giving him permission to excuse a jury on assigning his reason in writing might be passed.

An inquest was held on a woman of thirty-nine who died in Guy's Hospital the day after admission from anthrax. Her husband had been at work pulling about bales of China hides for the inspection of underwriters, as they were damaged by sea water. He said he washed his hands afterwards according to rules. He went home in the clothes he worked in, and his wife washed his neckerchief, but she had no abrasions whatever about her. The house surgeon intended to use the serum introduced by Dr. Legge, but when he went to the laboratory there was none in stock, and the woman died two hours later. The Medical Officer of Health for the district said he had investigated twenty-two cases, and most of them he traced to foreign hides. Verdict: Death by misadventure.

A verdict of death from misadventure was also returned on Wednesday at Middlewick concerning the death of Dr. G. W. Dutton, who had suffered from insomnia and was accustomed to take narcotics. Unfortunately he took an overdose.

An outbreak of typhoid fever has occurred at Basingstoke. On Tuesday the isolation hospital had twenty-two cases, practically exhausting its accommodation. On Wednesday seventy-eight cases had been notified, but only one death to that date. Preparations were being made to remove cases to the smallpox hospital.

## OUR VIENNA LETTER.

(From Our Special Correspondent.)

CHOLERA—PROPHYLAXIS OF LEAD POISONING—HOUR GLASS STOMACH—LUMBAR PUNCTURE IN CEREBROSPINAL MENINGITIS—SCLEROMA—UNUSUAL MUSCULAR CONTROL.

VIENNA, September 18, 1905.

Our country is again, as often before, threatened by a cholera epidemic. In Galicia, the province adjoining Russia, four cases of Asiatic cholera have been discovered, and three of the patients are dead. The scourge was brought across the frontier from Russia, and there is no doubt that the disease, starting in Arabia, Syria, and Mesopotamia, is advancing through Persia to the Caspian Sea and thence into Russia along the Volga. Although until now only isolated cases have been observed, the danger of a spread of the disease westward is urgent, and the health officers are making great efforts to prevent the development of an epidemic. In consideration of the present political conditions in Russia, and especially in Poland, it is hardly conceivable that efficient sanitary control will be possible, and it is not unlikely that the disease will spread rapidly through the valley of the Vistula and be carried into Austria by fugitives. According to past experiences an extensive morbidity is not to be apprehended until next spring, but this does not relieve the situation of any of its gravity.

The Bureau of Manufacturers has investigated the question of lead poisoning in lead and zinc foundries. All of the experts stated that workmen less than eighteen years old and all women should be excluded from the actual smelting operations. There was also unanimity of opinion concerning the necessity for restriction of the hours of labor at especially dangerous branches, opinions differing only in regard to the length of the periods of work and of rest to be established. It was also recommended that non-observance of the hygienic precautions imposed upon the workmen should be made a punishable offense. Dr. Hueppe, in discussing the matter of medical service in this connection, laid stress on the prophylactic obligations of the physician as opposed to his curative ones, and stated that improvement in the statistics of morbidity would have to go hand in hand with a very broad extension of the system of sanitary inspection. The necessity for medical examination of the employees before their admission into the smelting shops and for periodical re-examinations was universally conceded, and Prof. Sternberg advised that the intervals between inspections be made shorter in the case of men engaged in especially dangerous work.

Dr. L. Brauner presented before the Society for Internal Medicine a case of hour glass stomach in a woman forty-two years of age, diagnosed by means of the *x*-ray. The patient had for five months been complaining of abdominal pain, which was independent of taking food and was accompanied by vomiting of bitter fluid. On examination, aortic insufficiency and visible gastric peristalsis were discovered. On dilation with carbonic acid gas the lesser curvature was found to be placed above the umbilicus and the greater curvature a hand's breadth below it. The patient was then given a quantity of soft pudding which had been mixed with 35 grains of subnitrate of bismuth. A portion of the food lodged above the painful spot and did not sink to the bottom of the stomach until several deep inspirations had been taken. The *x*-ray examination then revealed the mass of food under the costal arch in the left mammary line, but it soon collected itself in the left hypochondrium, and neither through pressure nor massage could union of the two portions be effected, so that the diagnosis was confirmed.

Prof. Johann von Bokay read before the Royal Medical Society of Budapest a paper on the value of lumbar puncture in cerebrospinal meningitis. He reported two cases in which he had employed the measure for curative purposes. In the one, that of a twelve-year-old girl, the symptoms were not severe, and the removal of 30 c.c. of spinal fluid was followed by recovery. The other patient was a boy five years old, and in his case the gravity and subacute course of the process made it necessary to repeat the operation systematically. The result was satisfactory. In the course of two weeks the puncture was repeated seven times, and altogether 165 c.c. of fluid were removed. Bokay believes that in cases of cerebrospinal meningitis lumbar puncture is a valuable curative measure. In the discussion that followed Dr. Jul. Donath spoke of a man twenty-four years old who, without warning, woke up early in the morning with headache, then had epistaxis, and died in nine hours with stiffness of the neck, opisthotonus, and unconsciousness. This was a case of fulminating cerebrospinal meningitis. He further said that lumbar puncture never does damage, and therefore is always to be tried. The amount of fluid abstracted should be replaced by twice the quantity of salt solution.

Nasal scleroma is a rare condition, but recently cases of it have been observed more frequently, so that several clinicians have made it the subject of careful study. Dr. H. V. Schrötter has made a map showing the distribution of the disease. It is most often seen in certain parts of Poland, and from there it migrates into eastern Prussia, Galicia, and Moravia, where sporadic cases are seen. A case observed in Bavaria was found to have come from Moravia, but two cases in Switzerland were born in that country and had never come in contact with other sufferers from the malady. The disease appears to be becoming commoner, and cases from Galicia and Moravia reach Vienna, so that recently five or six have been observed. It would be very desirable to send suitable investigators to the regions in which the disease originates in order to study it more closely, and especially to determine its method of transmission. Scleroma is produced by Frisch's bacillus, an organism very similar to the bacillus of Friedländer. Morphologically these two germs have much in common, but they differ in their action on animal tissues. Whereas the tubercle bacillus is destructive in its action, and the bacillus of leprosy gives rise to destruction and production, in scleroma there is production of new tissue without any destruction. An interesting observation is the simultaneous occurrence of tuberculosis and scleroma in the same spot. Although most of the Viennese cases have come in from elsewhere, Dr. Schrötter knows of one patient who has never been out of the city.

Viennese medical circles have lately been thrown into astonishment over a man whose powers of muscular control are developed to a phenomenal extent. This individual possesses to a surprising degree the ability to make use of muscles of whose very existence the ordinary person is entirely ignorant. For example, he is able to throw his abdominal muscles into wavelike contractions, by means of usually passive muscles he produces a vibration of skin of the neck, and he also moves the larynx by means of its intrinsic muscles. He can dilate or contract the pupils at will, and once when on exhibition before Prof. Hoffa, on being challenged to simulate a scoliosis, he succeeded in producing a lateral curvature of the spine without any movement of the pelvis. A still more remarkable feat is his ability to stop his radial pulse by drawing the first rib up to the clavicle by means of the subclavius muscle, thus compressing the subclavian vessels. This remarkable individual can displace various organs—for example, his heart, causing the apex beat suddenly to appear in the most unexpected positions. His most remarkable performance is a dislocation of the small intestine. The diaphragm is forced upwards to such an extent that the lungs are compressed into about a half of their usual volume, and then the small intestine is moved up into the space thus formed, so that the vermiculation of the gut may be perceived through the thoracic parieties. The displacement of the intestine can also be verified by *x*-ray examination. The man discovered his singular powers by accident in the course of a physical examination by a physician, and since then through studies of his own and aided by hints from his medical friends he has developed these strange faculties to an incredible degree.

## OUR LETTER FROM PERU.

**(From Our Special Correspondent.)**

BUBONIC PLAGUE—YELLOW FEVER SCARES—SMALLPOX—NEGLECT OF SANITARY PRECAUTIONS—ANKYLOSTOMIASIS.

AREQUIPA, September 15, 1905.

THE lazaret for reception of cases of bubonic plague, in Mollando, was closed on June 25, the last five cases, fully convalescent, being discharged on that day. The number of patients admitted was 125. Of these 49 died. Yersin's serum was used liberally. Whether to that or to a comparative mildness of the epidemic is to be attributed the low mortality I am not in a position to say, as I saw only one case here. So far as I can ascertain, at least three patients came to this town; all died, but there was no case of contagion here. Was this to be credited to the excessive dryness of the air, the great amount of sunlight, the electrical conditions, or what? It cannot be laid to the credit of excess in preventive measures.

In Lima cases continue, and now there is some alarm as to yellow fever. Whether the latter is owing to cases having arrived in a steamer or steamers from the North, or whether it is owing to a physician of Lima having announced that he had caught specimens of the stegomyia, the press telling the public that this is the cause of yellow fever—not explaining that when yellow fever exists in a locality this is the intermediary host.

Smallpox has been very severe in Chile. That country suffers much in the epidemics of smallpox, owing to indifference to vaccination and revaccination. So far as I can remember, we always know for a month or two before smallpox arrives here that it is coming from the South. Do we then redouble our efforts to have all persons vaccinated and revaccinated? Not in the least until it actually arrives; then we bestir ourselves a little.

Ankylostomiasis is apparently widely distributed over the world, and will, from want of care, probably become more so. It has been recognized in the central parts of Peru, and now Drs. Escomel and Ricketts have shown me specimens of eggs and worms from patients who have come from the interior—the Santo Domingo gold mines. In one case the eggs of *Trichocephalus dispar* were found along with those of the *Ankylostoma*. I believe the association is not uncommon. As yet there seems to be no remedy for the trichocephalus, so we agree to class it as comparatively harmless.

## Progress of Medical Science.

*Boston Medical and Surgical Journal, October 12, 1905.*

**Resection of the Nasal Septum.**—L. E. White traces the history of the development of this now popular operation which, he finds, dates back to half a century ago. It was especially popularized by Krieg in 1898 and Killian in 1899, and brought prominently before American rhinologists by Freer two years ago. White's own operations number forty-five. He prefers weak solutions of cocaine, one-quarter of one per cent. for submucous injections and one per cent. for local application. The anterior vertical incision is chosen whenever possible. It can be extended backward, if necessary, at either top or bottom. The convex flap should be kept intact and the deflection removed through the vertical incision. Sutures are more or less optional. If the edges of the incision can be nicely approximated, tampons will keep them in place until they heal. They are decidedly advantageous if the vertical incision is extended backward. The time of the operation, from half an hour to one and a half hours, according to the difficulties of the case and the operator's natural skill. Under ordinary circumstances, healing of primary union occurs in one week. The operation is adapted to all types of spurs and deflections. White does not consider it advisable to operate on children under 14, the aged and infirm, tuberculous, or syphilitic patients.

*New York Medical Journal,* October 14, 1905.

**Reflex Irritations from Lesions in the Male Urethra.**—A series of cases is detailed by L. Bolton Bangs. He calls attention to the fact that the urethra has not only a urinary but also a sexual function, and that reflex disturbances are accordingly roused in both these domains of the animal economy. A urethral irritation may be reflected to the

muscular structures of the penis, the base and neck of the bladder, the prostate, and the seminal vesicles. This transmission takes place more frequently than is generally suspected. The bodily suffering caused thereby is not necessarily dangerous to life, but may gradually impair the patient's constitution and impair his vigor. Moreover, patients coming under this category are not by any means necessarily of the neurotic class. Most of those who are not are, however, generally of the class leading a "strenuous" life in our modern acceptation of that term. The lesion found in all is generally that of a localized urethral ulceration. Under urethroscopical examination it is possible to definitely expose the diseased area and make silver applications directly thereto. Under this procedure, together with the therapy naturally suggested by the conditions of each individual case, we may greatly ameliorate the patient's sufferings and often bring about a complete cure.

**Three Cases of Extraperitoneal Rupture of the Bladder Complicating Fracture of the Pelvis, with Recovery.**—The histories of these cases are given by J. R. Eastman. In Case I a man was caught under a falling refrigerator and the pubic arch was driven in on the right side, and operation revealed a large spicule of bone from the right horizontal ramus thrust through the anterior wall of the bladder. The rent extended around the right side of the internal meatus almost to the right ureteral orifice. Closed with chromicized gut, rubber drain placed in bladder, and the viscus lightly packed with gauze. In Case II the rectum and bladder were transfixed by some sharp object in a railway wreck. There was also a fracture of the anterior superior spine of the ilium, splitting the horizontal pubic ramus and a comminuted fracture of the right femur. The wound edges were trimmed and the same procedure followed as in Case I. The wound in the bladder floor leaked for ten days, after which all the urine was discharged in the natural manner. In Case III a crushing accident fractured the pelvis and ruptured the bladder. The pubic arch was driven in at both sides, causing fracture at the symphysis. The anterior wall of the bladder and roof of the prostatic urethra were torn for a distance of two and one-half inches. In this case, no attempt was made to close the wound in the bladder; a large drain was passed into the urethra and passed out through a suprapubic incision. The displacement of the depressed pubic arch was reduced by manipulation to the extent that while there was still deformity, there was no compression of urethra or rectum. This case became infected and a fistula developed at the right of the suprapubic opening. Another fistula appeared in the penile urethra, involving the membranous and prostatic portion, so that for a time the urine was discharged through all three of these unnatural openings. Simple curettage of these fistulæ and continuous catheterism finally effected their closure.

**The Relation of Certain Extreme Emotional States to Insanity.**—T. H. Kellogg notes that extreme emotions may suddenly cause mental disease, or, if prolonged, may gradually evenuate in insanity, of which they may constitute prominent symptoms. Extreme emotional instability and the insane diathesis may be vicarious and precede or follow each other in families. These hereditary extremes of emotion may be transmitted in direct line for several generations. The admitted relation between crime and insanity will be found, if traced to its ultimate source, to consist often in abnormally intensified emotion and correspondingly diminished self control. As types of extreme emotional states, may be cited the psychical condition arising out of passionate love between the sexes, violent and persistent hatred (shown for instance in the family feuds which pass on from one generation to another), uncontrollable anger, jealousy, fear, etc. In all these extreme emotional states the normal control of the feelings by the will is lost to a greater or less degree. Yet these emotional states may exist in persons having no distinct form of definite mental disease. It is precisely in these latter cases, when there have been legal infractions, that lawyers and laymen demand full infliction of punishment, while the enlightened medical expert recognizes the morbid stress and emotional duress under which the accused sufferers may have acted, and, therefore, favors the claim of modified responsibility.

*The Medical News, October* 14, 1905.

**The Teachings of Failures.**—F. L. Hupp records a series of cases referring particularly to post-operative hemorrhages. In one case of gall-bladder surgery, the patient passed on the third day after operation into a condition of sudden shock, though there was no evidence of internal bleeding. Death occurred on the sixth day and autopsy showed an extensive extravasation of blood. A second case was one of renal calculus. A tampon of gauze was carried down through the cortex into the renal pelvis, from which the stone had been removed. On the fifth day, owing to some indications of suppuration, the tampon was removed and profuse bleeding occurred, which proved fatal four hours later in spite of the reopening of the wound and ligature of the pedicle of the kidney. In another case a diagnosis was hurriedly made of cancer of the uterine cervix, but the case proved to be a sloughing submucous myoma. In still another case, one of supravaginal hysterectomy, foudroyant and fatal sepsis followed on the fifth day, though no failure in aseptic precautions could be determined. In a case of typhoid fever there developed on the eleventh day induration in the right iliac fossa. Incision revealed pus, and in the washing there escaped a tubular segment of the appendix. A suspiciously dark area was noted over the cecum, but the patient's collapsed condition forbade further interference. Two days later the dressings were saturated with a dark, offensive fluid, and on removal of the drainage strips decomposed blood clot welled from the wound. Death resulted the next day. Autopsy showed a gangrenous perforation of the cecum, while an eroded vessel at the base of one of Peyer's patches showed the site of bleeding. Several other interesting cases are narrated, and some references are made to the general subject of causes of sudden death, the statistics given being based on Lochtes' recent article on this subject.

**The Symptomatic Treatment of Tuberculosis.**—J. R. L. Daly refers to certain procedures he believes to be of value. Cough calls for sedative rather than stimulating expectorants. For pleuritic pain counterirritation is preferred, and often must be of considerable strength. A mixture of Croton oil, tincture of aconite, and tincture of iodine is suggested. This should be painted on lightly and not allowed to run. As to hypnotics, bromides are safest. If possible, a tepid bath may be given while hot bottles are applied to the extremities and a bandage placed about the abdomen to assist in the dilatation of the peripheral arteries and thus derive blood from the brain. Painful larynges may be cocainized just prior to the injection of food. Ethyl chloride sprayed in the larynx has proven serviceable in cases of tuberculous ulcers in the larynx. In the night sweating, the author has used atropine.

**The Gynecological Bladder.**—A. E. Gallant reviews 500 consecutive cases seen in one of the New York gynecological clinics and finds that 42.6 per cent. presented bladder symptoms. Some of the more unusual cases are epitomized. Six cases occurred (out of 213) in children under 16 years. In the 207 cases over that age the most common symptom naturally was frequent micturition with burning or cutting pain. Purulent urethrovaginitis was found in 25 per cent. Urethral caruncle once, hematuria three times. The histories of cases of trigonitis, pelvic peritonitis, "plaster-of-Paris" pelvis, pyosalpinx, cystocele, pregnancy, and uterine displacements as related to bladder disturbance are summarized. The author's conclusions are: (1) That frequent and painful micturition is met with in about one-third of females who apply for gynecologic advice; (2) that in 25 per cent. this is due to specific (gonorrhea) urethritis, often associated with vaginitis, etc.; (3) that but few cases of gonorrheic infection are met with after thirty-two years; (4) that vesical prolapse and intrapelvic or abdominal tumors are the most common factors after thirty years; (5) that uterine displacement, inflammation involving the broad, the uterosacral ligaments, the tubes and ovaries must be reckoned with, and relieved by appropriate measures before the bladder symptoms can be cured; (6) that as changes in the urine producing symptoms do not occur in more than 5 per cent. of all cases, after medical treatment has been tried for a time and found wanting, the pelvis should be explored digitally, and the anal region inspected, not infrequently the rectum and sigmoid as well. Whenever urinalysis points to calculi or infection in the bladder, ureter, or kidney it is our custom to pass the cystoscope and catheterize the ureter.

*American Medicine, October* 14, 1905.

**Patent Urachus.**—George Tully Vaughan gives a review of 52 cases of this rare condition, and reports one of his own complicated with stones in both kidneys, which were successfully removed at two subsequent operations. He explains the defective development in the embryo which results in the formation of patent urachus and of Meckel's diverticulum. He mentions four kinds of patent urachus: the complete, the blind, the blind internal, and the blind external, and these may be congenital or acquired, some of the acquired varieties being caused by pressure of urine in the bladder opening Wutz's valve (a small valve which guards the bladder opening of the urachus) and allowing urine to enter the urachus. He thinks the best treatment is to dissect out the urachus, and sew or ligate the stump or opening in the bladder, after the manner of removing the vermiform appendix. A short space is given to tumors and cysts of the urachus.

**Bilharzia (Schistosoma) Hæmatobium.**—Claude A. Smith reports seven cases found among the Boers and the South African negroes who were with the Boer Wa

Spectacle at St. Louis during the World's Fair, and who also appeared in Atlanta during March of the present year. Out of 45 specimens of urine examined the eggs of the Bilharzia hæmatobium were found in seven. It was not possible to examine more than 45 specimens on account of the short time the company remained in Atlanta, but many other members of the company gave histories indicating that they might harbor the parasite. The seven cases were apparently chronic, as macroscopic inspection did not indicate the presence of any blood or blood clots in the urine. Dr. Smith directs attention to the fact that the eggs are more or less cylindrical, one end being bluntly rounded, while the other runs to a point or "spine," and that the egg is not a flattened body as it appears to be when first viewed under the microscope. A description is given of the anatomy of the embryo and the hatching of the egg, the rupture of the shell apparently being due to the change in the specific gravity of the fluid surrounding the egg. In conclusion, the question is raised as to the advisability of permitting such a number of cases of this disease to drift about this country when there is uncertainty as to the possibility of contaminating our streams with this parasite, especially in view of the fact that we have no remedy for this disease.

**Hemorrhagic Typhoid with Typhoid Parotitis.**—B. D. Black reports a case, ending in recovery. The patient gave a history of an arrested pulmonary tuberculosis; no hemophilia or syphilis; total abstainer. Hemorrhages occurred about the seventeenth day of illness. Intestinal oozing was followed by oozing from mouth, throat, and nose, hematemesis, hemorrhage from bladder and urinary tract purpura involving right leg, and pressure points on posterior surface of body. Multiple hemorrhages for eleven days. A complicating parotitis seemed to have a marked effect on the hemorrhagic tendency. Medication is unsatisfactory, but saline solution is indispensable, as it renders the typhoid toxins less virulent and fills up the vessels. Camphorated oil as a last resort, when other stimulants failed, was given hypodermically, P. R. N., 15 to 30 drops. Its action was satisfactory. The literature on the subject is not exhaustive. This form of typhoid is rare and very little light has been thrown on the etiology by the recent advances made in blood pathology. Tuberculous cachexia (although not apparent) was possibly a causative factor in the case reported. A review of the literature and study of the case would suggest the following conclusions: (1) The hemorrhagic tendency in typhoid is probably increased by the fairly constant leukopenia which exists in uncomplicated cases. (2) The hemorrhages are usually by diapedesis in this form of typhoid. (3) As a result of the bacillemia, toxemia, or both, a degeneration of the intima of the vessels takes place, a pathological permeability of the vessel wall resulting. (4) The development of an acute inflammatory process (in this case a parotitis), with resulting leukocytosis, has a decided effect on the hemorrhagic tendency.

*Journal of the American Medical Association, October* 14, 1905.

**Brain Injuries.**—D. C. Peyton points out the indications for operative interference in cases of brain injuries. He holds that surgery is called for when there is evidence of hemorrhage or symptoms of compression, either from hemorrhage, depressed bone, or the presence of a foreign body, and emphasizes his opinion that in cases with symptoms of serious brain injury the danger to the patient of an exploratory opening with the observance of the highest degree of aseptic technic, is infinitely less than the unreasonable delay that is frequently permitted while waiting for definite diagnostic symptoms. He urges the importance of the surgeon watching the symptoms very closely from the beginning until he can assure himself that no injury has occurred within the cranial walls. Two cases are reported, one of gunshot wound with extensive comminution of bone, in which the fragments were removed and the wound cleansed by irrigation with normal salt solution, followed by recovery, and the second, of fracture of the base, terminating fatally.

**Uncinariasis.**—Claude A. Smith reports the experiments made on a human being to confirm those of Loossas in demonstrating the possibility of hook-worm infection through the uninjured skin. The experiments were made with great care to avoid the objections made to those of Loossas that there was possible infection through other sources. He thinks, and his reports seem to justify it, that the experiments conclusively prove that general infection may take place through the uninjured integument. That this is the only route he does not say, but he believes it to be the mode of infection in the great majority of cases.

**Iritis Tuberculosa.**—W. E. Gamble and E. V. L. Brown report a case of plastic iritis producing nodules which was identifiable by a process of exclusion and still more by the tuberculin reaction, as tuberculous. The treatment was by repeated injections of Koch's tuberculin and the use of atropine continued over six months and causing disappearance of the ocular conditions. There was evidence of a tuberculous focus elsewhere, to which the eye symptoms were probably secondary, as shown by a persistent rise of afternoon temperature, slight cough, and enlarged supraclavicular glands. The afternoon temperature continued after the disappearance of the eye symptoms. The authors give a detailed review of the literature of the use of tuberculin in the eye, and conclude that there is very little question of its diagnostic value. Their own experience leads them to advise the lowest possible dose on account of the profound general reaction they met with from a five mg. injection. Less can be said of its therapeutic value, but they think that many patients, like the one reported, can be helped.

**Pneumonia in the Young.**—E. F. Wells points out that pneumonia is most frequent in early childhood, and next most frequent in full maturity from 30 to 50 years of age. He limits the term to pneumococcal infection and the fact that the pneumococcus is present in the mouths and upper respiratory passages of probably 50 per cent. of healthy persons accounts for the frequency of the disease. He has never failed to find the pneumococcus in several hundred examinations of persons who have had pneumonia. But he has not found it in recently born infants, which accounts for the infrequency of the disease in the very earliest periods of life. Once the throat becomes infected, however, the child is liable to pneumonia. The symptoms, high temperature, rapid pulse and breathing, pain, cough, the well-known expiratory grunt, the loss of appetite and the physical signs are described. The chill which is usually conspicuous in adults is absent in young infants and is infrequent in young children. The child is usually dull and apathetic, surface pallor is the rule. The duration of the disease is shorter in infants than in adults, and unless some complication like empyema intervenes, usually ends by crisis, or less frequently by lysis, in a week or more. Serious complications are more frequent in children. The treatment necessarily must be more or less individual. The healthy child must be kept out of the way of the infected one. Exhaustion and too profound sleep must be guarded against in the infected child, and the fluids of the body, whether intravascular or extravascular, must be cleansed of the soluble toxins. The child with pneumonia should have plenty of liquids to drink and, in addition, salt solution by rectum if necessary. Theoretically, this washes out the toxins. In his practice the author gives moderately large doses of a reliable tincture of digitalis with the enemata if they are retained Other vasomotor tonics may also be given. For high fever and restlessness, he prefers tepid sponging, followed by alcohol, repeated as required. This failing, he uses guaiacol in suitable dosage to the thin skin of the flexures, supplemented by the ice cap at intervals. Oxygen inhalations are useful when the patient is not fretted by them. Strychnine aromatic spirits of ammonia, etc., may be used as required. The best medical attention and nursing and fresh air are required, and the child should be disturbed as little as possible.

*The Lancet, September* 30, 1905.

**A Case of Mitral Incompetency and Ascites Treated with Apocynum Cannabinum.**—The patient of A. J. B. Duprey was a black man about 40 years of age with mitral disease, enlarged liver, and ascites. He had been tapped many times, but with only temporary relief. Digitalis and iron seemed to be without effect, but to this combination was added the tincture of apocynum in one-minim doses. This was gradually increased until the dose reached ten minims t.i.d. but the quantity seemed to be somewhat irritating and it was reduced a little. Under the addition of this remedy the patient's general condition greatly improved and the quantity of urine passed was greatly increased. The author notes that apocynum is a powerful kidney stimulant Overdoses easily cause congestion of the renal structure and may lead to complete suppression. He believes that it deserves a further trial as a diuretic.

**The Influence of Nasal Obstruction on the Form of the Face.**—W. B. Parsons alludes to the great difference of opinion existing as to the relation in cause and effect of the high-arched narrow palate and nasal obstruction. The latter leads to the facies known as the "adenoid" but we may have the facies without adenoids; the latter without the former or both may coexist. It is generally agreed that nasal obstruction is the cause of the deformity, but it is not generally recognized that so much of it as affects the maxilla is due to anterior nasal obstruction, that the lower jaw is not really, but only apparently affected, and that the deformity at the bridge of the nose

alone is consequent upon posterior nasal obstruction. Variation in intranasal air pressure is potent enough cause when acting on mouldable bones, such as are found in the lymphatic, rickety, or other diatheses accompanied by malnutrition. The main point brought out by the author is that nasal obstruction, as related to the form of the face, depends upon the exact location of the obstruction. An anterior obstruction is at each inspiration productive of negative air pressure within the nasal chambers, and a corresponding increase of pressure on the outside of the face, while a posterior obstruction, that is, one situated in the nasopharynx, cannot exert any influence to diminish the air pressure in the nose and its accessory sinuses. On the contrary, this pressure is common with the general air pressure outside the nasopharynx (and if buccal respiration be also impeded outside the lungs) must become excessive, and its effect would be to depress the bridge of the nose, and to widen it. Finally, he notes that the adenoid operation is not always successful, so far as affecting the shape of the parts is concerned. Symptoms previously present may continue. They are often due to hypertrophic rhinitis. To this latter lesion is to be ascribed the persistence of the habit of mouth breathing after the adenoids have been removed. The evidence of this is often stamped on the face, and the attempt to overcome it is too often an unjustifiable harshness to the child.

**Secondary Effects upon the System, which May Be Produced by Chronic Enlargement of the Tonsil.**—The views of H. B. Gardner have been suggested to him by his experiences as an anesthetist. He believes that some cases of varicose veins of the legs and of hernia, are caused by the presence of tonsillar enlargements. He believes that in the former state the chronic obstruction to free respiration (caused by the tonsils), and to oxidation of the blood produces a certain degree of chronic engorgement throughout the systemic veins, and that thereby a contributing cause to gradual dilation of the veins in the legs is set in motion. In hernia, intraabdominal pressure is the chief exciting factor, and in case of enlarged tonsils the patient will exhibit powerful contractions of the abdominal walls during cough or labored breathing. Such patients are apt to lie prone on their faces in bed with the forehead upon the pillow and head to one side, and the mouth open, in order that the tonsils should hang forward and free the breathway. Consequently the condition of the tonsils should always be ascertained in giving patients with varicose veins or with hernia, and if enlarged, their removal is the first logical step toward the cure of the varicosities and hernia. The removal of this cause of intravenous and intraabdominal pressure often has a distinct prophylactic value, with reference to the two conditions named.

**A Case of Tuberculous Meningitis Treated with Iodoform Ointment.**—The patient of H. C. Wilson was a boy of six years. One brother had previously died with what was regarded as tuberculous meningitis, and there was on the maternal side a tendency to tuberculosis. The patient developed the typical features of this form of meningeal inflammation, and on the fourth day an ounce of iodoform ointment, representing 15 grains, was rubbed in over the scalp and the back of the neck, and this was repeated every eight hours. Two days later the child began to improve and the crisis of the disease seemed to have been passed by the end of a week. The further progress of the disease was without incident. The ointment was applied for between two and three weeks. The case seemed hopeless until its use was begun. The accuracy of the diagnosis was based on the family history, and the patient's symptoms, viz., Semi-coma, retraction of the head. Kernig's sign, tache cérébrale, and muscular twitchings.

*The Lancet, October 7, 1905.*

**Chronic Paralysis of the Intercostal Muscles as a Primary Cause of Dropsy.**—The patient of G. W. Howland was a lad of seventeen years, who was injured four years ago by a blow on the neck, producing a dislocation of one of the cervical vertebræ. Myelitis followed, affecting the fifth, sixth, seventh, and eighth cervical regions of the cord, being probably secondary to small hemorrhages arising from the concussion due to the injury. Sensation was rapidly recovered, but atrophy of the muscle groups represented in this region gradually occurred, accompanied by a spastic paralysis of the legs. Respiration during these four years had been carried on entirely by the diaphragm, since the intercostal as well a the abdominal muscles were paralyzed; and this was the more remarkable when it is noted that the boy suffered last year from an attack of acute bronchitis, with consequent difficulty in expectoration. It is also interesting to note that the patient was able to cough feebly, but in doing so was unable to fix the chest, which expanded upwards with the forced expiration. In consequence of this purely diaphragmatic respiration there was diminished expansion of the upper lobes of both lungs and this had acted in the same manner as emphysematous or fibroid pulmonary diseases, and caused obstruction to the venous circulation and to the right side of the heart, although the venous obstruction might be partly due to a diminution in the negative intrathoracic pressure. During the last few months the legs had become greatly swollen, the dropsy being due mainly to the conditions outlined above, rather than to the diminished vasomotor tone, since the complication had only recently appeared. Following this very intense edema had appeared in the neck, face, and eyelids and latterly in the uvula and larynx, and the distress in breathing had been great. Rest in bed led to a rapid improvement in the dropsy. At the time the case was reported, there was no definite cardiac enlargement and no murmurs, but the heart was subject to strain, owing to the extreme action of the diaphragm, while there was a reduplication of the second sound on the left sternocostal area.

**Acute Dilatation of the Left Ventricle.**—A case occurring in a diphtheritic boy of five years, is reported by T. Nicol. He was so slightly ill that no antitoxin had been given. On the diphtheria supervened a mild scarlatina. Suddenly, six weeks after the diphtheria and three after the scarlatina, he was seized with syncope with vomiting, almost imperceptible pulse, and moderate fever. Examination of the heart (found normal on the day previous) showed extreme left-sided dilatation. The apex beat was diffuse and wavy, visible in the fourth, fifth, and sixth interspaces from the nipple line to the sternum. On auscultation the beats numbered 110 per minute, and were markedly intermittent, the first sound at the apex almost inaudible but without definite murmur, and the second much accentuated and occasionally reduplicated in both pulmonary and aortic areas. On percussion, the left border extended almost three fingers' breadth beyond the nipple line, the right being in its normal position. No reason could be assigned for the attack, since the child had not been sitting up or making any unusual exertion. That evening, however, the urine was found to contain albumin and blood in large amount, with numerous blood and granular casts. He was freely stimulated with brandy and hypodermic injections of strychnine, but his condition remained extremely critical for more than a week. After that time both the nephritis and the cardiac condition improved under treatment, and after a prolonged stay in hospital he was discharged with only a faint trace of albumin in the urine, and a heart in which the most careful examination could detect nothing abnormal, the pulse strong and regular, the sounds pure, and the left border one finger's breadth inside the nipple line. The unique feature of the case is that the dilatation did not follow (as it usually does) after some overexertion, but was rather coincident with the onset of a scarlatinal nephritis.

**Observations on the Thymus Gland in Children.**—Some interesting observations have been made on this subject, by J. M. Fortescue-Brickdale. His conclusions are summarized in the following statements: (1) The usual weight of a microscopically normal thymus in a child under one year is under 100 grains. (2) Children suffering from "primary atrophy" or marasmus commonly, but not always, exhibit fibrotic changes in the thymus; the weight and size of the organ are also usually diminished. (3) Children suffering from "secondary atrophy" exhibit similar changes but they are not so constant. (4) Possibly some other factor than mere malnutrition or starvation may produce these fibrotic changes, as in a case where pure starvation was produced by congenital stenosis in the alimentary tract they were not observed. (5) In cases of acute illness in children fibrosis of the thymus may accompany general wasting. It is difficult in these cases to exclude previous disturbances of nutrition, at any rate among hospital patients. (6) Enlargement of the thymus and other lymphatic structures in the body may occur as the result of acute toxic absorption (as in diphtheria) or a more chronic condition (as in lymphatism). In these enlarged thymus glands eosinophile cells are numerous, but no special types are peculiar to either class. (7) In some conditions, especially in tuberculosis, cells with basophile or neutrophile granules seem to replace the eosinophiles. (8) In congenital heart disease eosinophiles are not found in the thymus. (9) True hyaline degeneration very occasionally occurs in Hassall's corpuscles. (10) Fatty degeneration of the cells is common and appears often to affect the peripheral zone of the lobules.

**A Case of Motor Aphasia Without Agraphia.**—The case is reported by Byrom Bramwell, whose patient was a married woman, aged 27 years. The aphasia was purely motor. Certain defects in writing in the early stages of the case, were clearly due to defects in manipulating the pencil and not to a true aphasic defect. The onset of symptoms was sudden, due to either embolism or hemorrhage. In favor of the former are adduced the patient's age, a mitral

stenosis, the sudden occurrence during a febrile attack, attended with sore throat and phlebitis, and a very brief coma at the outset. The embolism probably affected the left middle cerebral artery or some of its branches, but the loss of sensation on the right side of the face, the right deafness and anosmia, suggest, perhaps, a lesion of the posterior end of the internal capsule. Against this localization is the fact that the leg was much less paralyzed than the arm and face. So far as the paralysis is concerned, and on the assumption that embolism of the left middle cerebral artery existed, the lesion would appear to have been both cortical and subcortical, a softening of the left motor area at its lower end. For two weeks after the onset of symptoms, the patient uttered no spoken word, though she tried so to do, but she was taught in due time to repeat vocal vowel sounds, and gradually recovered the power of speech. The author knows of no other case in which such complete motor vocal aphasia was associated with such perfect ability to write.

*British Medical Journal, September* 30, 1905.

**The Opening of Peritonsillar Abscesses.**—R. McClelland describes a method of emptying an abscess in this situation. The patient was an epileptic girl in whom, after scarlet fever, a large peritonsillar abscess had developed. She could with difficulty open her mouth wide enough to admit a finger. When the abscess fluctuated the writer opened it by driving a Paget knife through the soft palate into the center of the swelling. The patient slept fairly well that night, but the wound soon ceased to discharge, the abscess wall became tense, and the patient again could neither speak nor swallow. The writer sprayed the soft palate with a 10-per cent. cocaine solution, and passed a trocar and cannula into the center of the swelling. The patient held the cannula with her teeth while the trocar was withdrawn and one end of a piece of rubber tubing was slipped on, the other end being attached to the nozzle of the syringe. At one stroke two ounces of pus were withdrawn with instant relief. The patient had not had a fit during her illness of thirty days, but the epilepsy returned as recovery took place. The abscess completely disappeared with simple evacuation. Pus cells and numbers of diplococci were found on films that were made from the contents of the syringe. By this method the patient does not need to be moved if very weak, for the abscess can be evacuated even in dorsal decubitus. The mouth is not flooded with pus and little room is needed for working. If the distance between the soft palate where the puncture is to be made and the lower incisors is measured off on the trocar and cannula this method should be free from danger.

**A Case of Maladie De Tic Convulsive.**—James Johnson describes this case. The movements of the patient, a man twenty-eight years old, were quite different from those of an ordinary case of chorea. The involuntary muscular movements were well marked, affecting chiefly the brachial muscles of the face and arms. The patient often raised his hand, blowing at the back of it as if there were a piece of soot on it. He also spat on it in a convulsive manner. He sometimes suddenly jerked his head to one side without raising his hand, and then spit convulsively on the floor or on any one near and would often bark, and at times say "blast" or "damn" in quick succession. These words were frequently indistinct. At table he beat a tattoo on his plate with his knife or fork or spoon. When rising from a chair he shuffled his feet before commencing to walk as if preparing for a step dance. He was greatly attracted by lights in the street at night. Not only did he then indulge in his curious habits, but as he walked he turned his head round to keep his eyes fixed upon the light. At times he staggered as if he were drunk. He had imperative ideas which forced him to execute certain movements. He felt compelled to satisfy that impulse. The movements were always worse when the patient was busy. Otherwise the patient was in perfect health, always attending to his business.

*British Medical Journal, October* 7, 1905.

**Strain as a Factor in Cardioaortic Lesions.**—H. B. Anderson declares that we need only recall how often it happens that the cardiac muscle is insufficient to withstand the requirements of ordinary quiet life, to understand how powerful a cause of mischief severe exertion may be. As to the effect of repeated or habitual exertion within wise limits, it is known that athletic and other exercises, when properly regulated, are beneficial to the heart by producing physiological hypertrophy of the organ and lowering the average of peripheral resistance. Clinically speaking, the military surgeons first directed attention to, and carefully investigated the effects of overexertion on the heart. It was found that many cases of cardiac trouble existed in the otherwise healthy soldiers. Aside from certain modifying conditions in soldiers' surroundings, which appear to increase the liability to injury from overstrain, the tendency of overexertion in civil and military life is to produce cardiovascular lesions. Exercises in which the legs are employed are especially likely to be associated with cardiac trouble. These cases of overstrain may be classified as acute and chronic. The former is generally noted in the young, weakly, or untrained as the result of severe or prolonged exertion. The "irritable" heart is more often the result of repeated overexertion developing gradually. Mechanical stress not only injures the myocardium, but it is also a cause of aortic valvular lesions. It may even damage sound valves. The writer then presents the history of various cases which illustrate the effects of strain in a number of cases. He points out the extreme danger to older people of indulging in unusual exercise which could have been taken with impunity in earlier years. In the obese there is a condition of chronic overstrain, for there is a relative disproportion between the size of the heart and the work it has to perform. This state of affairs follows from the fact as stated that the size of the heart is proportionate to the size of the skeletal muscles, but the work of the heart is proportionate to the bulk of the body. The toxemia of the acute infective diseases produces serious changes in the myocardium and causes unwarranted exertion to be followed by the most serious consequences. In all cases of acute infection it must be admitted that a broad view of the pathology of the disease is the only safe guide to an appreciation of the state of the myocardium, even in the absence of all symptoms and physical signs of its involvement.

**The Cause of Angina Pectoris.**—James Mackenzie concludes that since angina pectoris occurs in lesions of great diversity, some condition common to all must be the cause of the symptoms. The fact that angina pectoris appears only after the heart muscle has been long exposed to excessive strain points to the cause being situated in the muscle. All the functions of the muscle fibers save that of contractility can be shown to be intact in many cases that suffer from angina pectoris. The alternating action of the heart is a demonstrable sign of exhausted contractility, and its presence is always associated with symptoms that are included in the symptom complex of angina pectoris. The same exciting cause—extra strain on the heart—may provoke both the angina pectoris and the alternating action, and both may disappear with removal of the cause. The inference to be drawn from the consideration of these facts is that the symptoms that are included in the term "angina pectoris" are so closely associated with an impairment of the function of contractility of the muscle fibers of the heart that in all probability angina pectoris will be found to be an evidence of the impairment of the function of contractility.

**The Albuminuria of Adolescents.**—Clement Dukes declares that the albuminuria of adolescents appears to arise from the want of adjustment of the cardiovascular system to changes of blood pressure. The nerves do not exert an effective control over the blood vessels, and thus serum-albumin is allowed to transude through the over-distended capillaries of the kidneys. In other words, there exists a congestive neurosis. The main features of this affection as enumerated by the writer are its intermission, the variability in the amount of albumin present from time to time, its duration, and the infinite variety of causes and the slight nature of each. The writer believes that when this condition is recognized and treated, there is little likelihood of its proving the precursor of organic disease of the kidneys even when it has existed for many years. The manner of life must be carefully regulated. Work must not be excessive. Daily exercise should be recreation rather than physical drill. Thus pleasurable sensations will increase the tone of the whole nervous and vascular system. The adolescent requires more food than the adult, and the girl more than the boy, on account of her greater rapidity of growth. The scavengers of the body should be so disciplined as to be brought under the habitual control of the will. Natural action should not be replaced by continual aperients, for the habitual use of the latter will encourage sluggishness of the intestines and tend to convert a temporary inactivity into a permanent abandonment of function.

*Berliner klinische Wochenschrift, September* 25, 1905.

**The Bacteriological Diagnosis of Cholera.**—Dunbar describes a method of performing the agglutination reaction with cholera organisms by means of which it is possible to make an approximate diagnosis in suspected cases very quickly. It is often a matter of great importance as regards prophylactic measures to be able to arrive at some conclusion concerning doubtful cases of intestinal disorder promptly, yet the ordinary agglutination reaction requires eight to nine hours before the agar colonies have developed sufficiently to make a test possible. The author tried the plan of using the stool itself in the fol-

lowing way. A drop of pepton solution is put on each of two cover glasses and a small flake from the suspected stool is rubbed up in each. Then to the one is added a drop of normal rabbit serum diluted fifty times, and to the other a drop of cholera serum of high valency diluted 550 times. The preparations are placed in hollow slides and examined. If cholera vibrios are present they will be found in motion in the normal serum drop, but not so in cholera serum drop, the difference becoming evident very promptly. If the preparations are placed in the incubator and examined at half hourly intervals active development and motion will be observed in the normal serum drop, and after a half hour agglutination will begin. Material containing only cholera-like vibrios can be readily identified in this way, but the question is more difficult when true organisms and some of the similar vibrios are together. With practice the distinction appears quite plainly, however. The author does not consider this plan an adequate substitute for the older cultural methods, but advises it as a useful time-saving measure, permitting the expression of an opinion within a very few minutes after the suspected stool is received.

**The Treatment of Gonorrheal Arthritis by Means of Bier's Congestion.**—Hirsch reports on the results obtained in the treatment of thirty-six cases of gonorrheal arthritis by means of Bier's stagnation hyperemia. The results, as far as the relief of pain and simplicity of application goes, were very satisfactory, but the average duration of the treatment was longer than that under the older methods. The functional results, also, it was found, were equally good before the Bier treatment was introduced. A prominent feature of the treatment, however, was the promptness with which the pain was relieved.

*Münchener medizinische Wochenschrift, September 26* 1005.

**The Migration of Lymphocytes.**—Schridde believes that he has been the first to furnish indisputable evidence of the power of migration of the lymphocytes in man. His observations prove that the lymphocytes have the ability by their own movement to penetrate vessel walls and enter these from the surrounding tissues. The question of whether the converse is also true and whether the lymphocytes can emigrate from the blood, that is, whether they retain the power of migration after reaching it, is still undecided, but the author believes that there is no evidence against this assumption. The crucial point in his study is stated to be the use of a special stain which is not described in detail in the present communication, by means of which it is possible to differentiate the lymphocytes clearly from leucocytes in sections of tissue. The method comprises staining with azur ii eosin and subsequent treatment with acetone. By using this differential stain in sections of mesenteric glands from a case of congenital leukemia the author was able to demonstrate large numbers of lymphocytes *en route* from the tissues into the lumen of capillaries.

**An Unusual Complication of a Diagnostic Excision.**—Steinbuchel says that all authorities are agreed that successful treatment of uterine carcinoma depends on early diagnosis, and that this often requires excision of bits of the suspected tissue. This little operation is one that the general practitioner is with propriety urged to do for himself, but that even this procedure, slight as it seems, is not without danger is shown by a recent misadventure of his own. A patient he had been treating for pelvic disorders for some time developed a suspicious erosion of the cervix. She was taken to a private hospital and in an aseptic operating room, after shaving and disinfecting the vulva and vagina as for a major operation, a wedge was excised from the cervix, and as there was moderate hemorrhage two silk sutures were applied. The same night the patient had a chill and high temperature, and though the sutures were at once removed and the wound was vigorously cleansed, she developed a septicopyemia, which ended fatally after four weeks of illness. The author ascribes the unfortunate outcome of what in itself was a trifling affair to the fact that one or two ovules of Naboth with turbid contents were opened by the incision and on this account it was a technical error to close the little wound with sutures. He therefore advises in all cases the omission of sutures and the control of bleeding by packing. The pathological report read carcinoma, but the condition might easily have been benign, and yet the fatality would have occurred just the same

**A Simple Method for Measuring the Temperature of the Skin.**—Gaertner says that so far no satisfactory method for obtaining the temperature of the skin has been devised. The inherent difficulties of the problem are great because any prolonged contact of the instrument with the skin changes the heat radiation of the skin, and the instrument itself is also subjected to the influence of air currents. The author's instrument consists of a thermometer having the mercury chamber flat and at right angles to the stem. The part of the bulb not in contact with the skin is protected against the air by a cover of hard rubber. In making a temperature determination two glasses of water, one warm and one cold are used. On applying the instrument to the skin the mercury column will immediately either rise or fall. The thermometer is alternately heated and cooled by touching it to the exterior of the vessels of water before placing it on the skin, within constantly narrowing limits as indicated by the rise or fall of the column, until it appears that the correct reading has been obtained. The error, it is estimated by the author, is not over .2° C. For convenience, instead of using one long thermometer it is recommended to employ two short ones, one calibrated from 20° to 32° C., and the other from 30° to 42° C. The former is used if the skin appears cool, the other if it is warm.

*Deutsche medizinische Wochenschrift, September* 28, 1905.

**The Removal of Foreign Bodies by Means of the Esophagoscope.**—Hacker is a warm advocate of this method of removing foreign bodies from the esophagus, and says that it is not yet practised to the extent it deserves. It is a procedure that general surgeons should learn to use just as they are now familiarizing themselves with the cystocope. Not every case is adapted to it, however, and the surgeon should always be ready to perform an esophagotomy immediately in case of failure with the esophagoscope. It is a great advantage for the patient to be in the care of a physician who is trained to every form of procedure that may become necessary. The author's total number of cases is now thirty-eight, and he says that he has never been obliged to perform esophagotomy on account of lack of success with the esophagoscope. He describes in brief his last twelve cases. The foreign bodies were bone fragments, artificial teeth, pieces of meat, and fruit stones. In seventeen of the author's thirty-eight cases the foreign body was removed from below the bifurcation of the trachea. With adults he does the operation under local anesthesia with cocaine, but children do better under a light chloroform narcosis.

**Sciatic Scoliosis.**—Lorenz in discussing this deformity says that there is first a primary curvature in the lumbar region with its convexity toward the diseased side, and secondarily there is a curvature in the dorsal region with its convexity toward the opposite side. It is the latter that has usually been regarded as the most conspicuous feature, and this is termed a heterologous or crossed scoliosis. The deformity is, however, essentially a rigid spastic primary lumbar scoliosis, and this is developed through curvature of the lumbar spine owing to reflex muscular spasm having for its object relaxation of the lumbosacral nerves in order to protect them from painful tension. The process is therefore a conservative one and should be fostered, not corrected, and efforts to dissipate the curvature result only in great pain to the patient and prolongation of the disease. During the painful stage the author advises the application of a plastic dressing from the thorax to the ankle of the affected leg, the patient being in the position which permits greatest relaxation and therefore greatest comfort. This dressing may be kept on for weeks or months, and then when the pain has ceased the usual treatment of massage, gymnastics, stretching of the knee, supporting body brace, etc., may be resorted to for the purpose of overcoming the deformity.

### *French and Italian Journals.*

**Contribution to the Study of Epithelioma of the Vulva.** Georges Mauxion calls attention to the rarity of both epithelioma and carcinoma of the vulva, sarcoma being far more frequent. There appears to be about one case of vulvar cancer to thirty-five or forty cases of uterine cancer. Goldschmidt in his thesis in 1902 reported two hundred and thirteen cases of vulvar epithelioma, as the entire number known up to that date. It is interesting to note that although malignant growths of the vulva are very rare, they are, nevertheless, nearly always primary. It is only exceptional that they are secondary, and more rarely still that they occur as an extension of a malignant neoplasm of the genital tract which has traveled from above downward. Malignant growths of the vulva, like the majority of other cancers, occur for the most part in older women. The most susceptible period seems to be between the ages of forty and sixty. The writer adds to those already reported two unpublished cases. A variety of this affection that is especially grave is that which is found about the meatus called periurethral cancer, on account of the rapidity of the appearance of the phenomena of retention of urine, vesical infection, and pyelonephritis. The prognosis of these neoplasms is grave. But, if the growth is removed in time, it may not recur for many years, and perhaps never. Treatment consists of thorough surgical removal of the diseased tissues. In inoperable cases, curettage of the fungous

patches with cauterization by the red hot iron, will often give relief. Recourse may also be had in these cases to radiotherapy.—*Revue Française de Médecine et de Chirurgie*, September 11, 1905.

**Electricity and Chronic Constipation.**—Paul Ch. Petit speaks of the good effects of electricity in cases of chronic constipation. In instances of temporary constipation, the return of the ordinary régime and purgatives generally suffice to overcome the condition. But, for the chronically constipated individual, retention of fecal matter is the habitual state. Certain individuals do not have a daily evacuation of the bowels, this condition being normal for them. They cannot be said to be troubled with constipation any more than those individuals who have two stools a day regularly, can be said to have diarrhea. The personal equation must always be considered. Besides the number of evacuations, their quantity and composition must also be considered in these cases. For many, constipation is a real menace. It is rarely that these patients are in good condition. Rectal affections are very common among them—fissures, hemorrhoids, and so on. The digestion is generally out of order. Vertigo, temporary deafness, and headache torment them. They are not capable of enduring prolonged labor Little by little neurasthenia develops. This affection never appears suddenly. It is common to middle age. Women seem to be affected more often than men. These patients—not considering the divers clinical aspects—may be grouped into two large classes. In the first spasm of the intestine is the prominent condition, in the second, atony is paramount. The writer concludes his paper by discussing the action of the galvanofaradic method of giving electricity. The galvanic current acts on the intestine through the mediation of the abdominal nervous system. The current abolishes spasm, and increases the secretion of the intestinal glands. The faradic current, light and rapid, offers a true massage to the parts treated. It thus stimulates the circulation. By this method, then, all of the abdominal tissues are reached. In many cases, from fifteen to twenty treatments are sufficient. The results of this method of treatment have been encouraging.—*Gazette des Hôpitaux Civils et Militaires*, September 7, 1905.

**The Preferred Operation in the Radical Cure for Crural Hernia.**—Salvatore Salinari tells us that there is no unanimity of opinion as to the best operation for the radical cure of crural hernia. There is slight tendency to recurrence of crural hernia, and it is usually small in size. On account of the fibrotendinous nature of the tissues, which allow of the passage of the hernia, and the peculiar conformation of the parts it is difficult to obtain exact coaptation of the parts and a perfect union, such as to hermetically seal the opening, and give a perfect obliteration of the crural canal. The author believes that the operation that corresponds best to the needs of the patient is the operation of Bassini. It avoids the formation of an acute angle, which might press upon the veins of the part, and give rise to thrombosis of the vein and embolism in the pulmonary artery. The only objection is the difficulty of preventing the existence of an infundibulum, which might cause recurrence.—*Giornale Medico del Regio Esercito*, August 31, 1905.

*Annals of Surgery, September, 1905.*

**Dry Iodine Catgut.**—The results of elaborate experiments are presented by A. V. Moschcowitz, who has used the iodine gut for some time, but has been somewhat disappointed in its lack of suitable tensile strength. He became convinced that this was due only to its long-continued immersion in the iodine solution (Claudius method). He has found that the objection named is obviated if the gut be removed from the solution at the end of eight days and preserved in a dry sterile vessel. For the catgut thus prepared he claims the following advantages: (1) The "dry" iodine catgut is absolutely sterile. (2) It is impossible to infect it by ordinary means. (3) Its inhibition with iodine is not sufficient to act as an irritant upon the tissues. (4) Its tensile strength is superior to raw catgut and to that prepared by the sublimate-alcohol method. (5) It is easily and cheaply prepared. (6) It is absorbed only after it has served the purposes for which it was intended.

**A Contribntion to the Knowledge of Endothelioma and Perithelioma of Bone.**—W. T. Howard, Jr., and G. A. Crile summarize the histories of nineteen previously reported cases of this unusual lesion and four personal cases, analyzing the material thus assembled. Their first personal case was that of a man, aged sixty-five years, who had a primary perithelioma of the left humerus. Symptoms began with pain which lasted two years, and then, while exercising, a transverse fracture occurred. This was followed by non-union, and metastasis occurred on the tip of the nose. Examination of a bit of tissue removed from the latter gave the diagnosis of perithelioma. Amputation of the humerus and nasal tip was done, but the patient developed some obscure pulmonary symptoms immediately thereafter, and died rather suddenly on the third day. A detailed report is given of microscopical findings. The second patient was a man of thirty-one years, who, in January, 1899, had a spontaneous fracture of the middle third of the left humerus. The bone apparently knit, but nine weeks later a second fracture occurred at the same place. Shortly after the first fracture the patient noticed a small nodule over the right temporal bone. He died of exhaustion about seven months after the first fracture of the humerus. The third case was one of primary endothelioma springing from the lymph spaces and channels of the lumbar vertebræ, clavicle, and ribs, with extensive metastases, chronic cholecystitis with gallstones and thickening of the gall-bladder occurring in a man of forty-five years, who died in a condition of coma. The last case was that of a girl aged eleven years who had a primary lymph endothelioma of the left femur with metastasis in the inguinal glands. No autopsy was obtainable. The authors express no positive opinion as to the etiology of these growths, although they say that in certain of their investigations they were impressed with the readiness with which the proliferation of the endothelium of the lymphatics would be explained by the assumption of the action of microorganisms or their toxins. In a general way the clinical history and aspects of these growths resemble the general type of osteosarcoma. They are apt to occur at the later periods of life, however, resembling in this respect the carcinomata. The long bones are most often involved. Pulsation in the growths may suggest aneurysm. From a clinical standpoint diagnosis cannot be definitely established.

**Malposition of the Appendix as a Cause of Functional Disturbances in the Intestine.**—Three cases are noted by J. A. Blake. The first was that of a woman of forty years, with attacks of pain in the right lower abdominal quadrant. Constipation, flatus, etc.; some tenderness over the appendix, but no palpable mass. The appendix was of the third (Treves) type, two and a half inches long. Mesoappendix was very short, suspending the appendix and cecum well up under the ileocecal junction, causing in its appendix attachment a sharp bend in that organ, narrowing its caliber. No signs of recent or old inflammation; mesoappendix divided, cecum straightened out; appendix removed; uneventful recovery; entire freedom from subsequent painful attacks. The second case was that of a man, aged forty-seven, with the same general symptoms, except that diarrhea has been present in several of the attacks; slight appendical tenderness. Operation showed the appendix implanted at the axial end of the cecum, four inches long, extremity slightly bulbous, no stricture or sign of inflammation. The mesoappendix was short and suspended the end of the cecum, as in the first case, up under the ileocolic junction. Appendectomy allowed the cecum to regain its normal relation, and was followed by complete relief. Case three was that of a nurse of thirty-six years, who had suffered for two years or more with constantly recurring pains in the right lower quadrant, but not of sufficient violence to keep her off duty. There had been no signs typical of inflammation. Operation revealed an appendix four inches in length of the third type of implantation and in the retrocecal position, the end of the cecum being rolled up under itself. Operation in this case was also followed by complete relief. This peculiar position of the appendix is explained by abnormal developmental sequences.

**Contusion and Laceration of the Mucous and Alar Ligaments and Synovial Fringes of the Knee-Joint.**—C. P. Flint gives the histories of four cases illustrating the fact that "chronic knee" cases often give no history or present no physical sign enabling a diagnosis to be made before the joint is opened. The operations in his cases revealed such lesions as are indicated in the title of his paper. The author takes up the question of the danger of opening the knee-joint, saying that one feels justified in abdominal section because of the improvement in method, and because one is supported by the knowledge that the peritoneum is well able to take care of a wide margin of error on the operator's part. This safety factor does not obtain in the case of the knee-joint, however, as most surgeons know to their sorrow. Moreover, says the author, "there is another reason, also, why we do not care to risk operating on the knee for exploratory purposes. An individual with an infected peritoneum does one of two things—he either gets well and does not show much evidence of what he has been through, or he dies. The man with an infected knee does the same—he recovers or he dies. The calamity of the fatal cases is equally great, but the recoveries differ; the man recovering from an infected knee is apt to have a stiff joint or have had an amputation—memoranda at all times connected in the individual's mind, throughout his life, with the unfortunate surgeon's name and skill." As to the results in the author's own cases, it is stated that all four patients had two apparent subjective symptoms, pain and limitation of function. In all, these two symptoms were for the time relieved.

# Society Reports.

## NEW YORK STATE MEDICAL ASSOCIATION.

*Twenty-second Annual Meeting, Held in New York City, October 16, 17, 18, and 19, 1905.*

(Special Report to the Medical Record.)

THE PRESIDENT, DR. J. RIDDLE GOFFE, IN THE CHAIR.

FIRST DAY—MONDAY, OCTOBER 16.

AFTER the meeting had been called to order by the President, the reports of various committees were presented.

**Bill Favoring One Medical Examining Board.**—Dr. E. ELIOT HARRIS, chairman of the Committee on Legislation, introduced the following resolution, which was unanimously carried:

*Whereas,* The number of bills introduced in the Legislature creating examining boards for some special department of medicine is increasing each year, and as the various bills provide a special examination which differs from the examination now required to obtain a license to practise medicine in this State, and in view of the fact that the medical profession is called upon to be active in Albany each year to protect the public health from such pernicious legislation, be it

*Resolved,* That the New York State Medical Association believes that the time has arrived to create a sentiment in the medical profession, as well as in the Legislature of this State, in favor of one medical examining board instead of the three separate examining boards now provided in the law, and to counteract the growing tendency in the State Legislature to create special examining boards for some of the popular medical fads;

*Resolved,* That the Committee on Legislation of the New York State Medical Association shall be empowered to confer with other medical bodies in preparing a bill to be introduced at the coming session of the Legislature embodying the recommendations contained in these resolutions.

**Bill to Abolish the Coroner System.**—The following resolutions were also adopted:

*Whereas,* The New York State Medical Association believes the coroners' system in this State, and especially in the City of New York, is antiquated and should be replaced by one more modern than the system which now prevails, therefore, be it,

*Resolved,* That the Committee on Legislation be instructed to investigate the question embodied in these resolutions, and embody the result of its work in the form of a bill to be introduced in the Legislature of 1906.

*Resolved,* That the Committees on Legislation of the District Branches and County Associations are requested to cooperate with the Committee on Legislation of this Association in carrying out the recommendations contained in these resolutions.

DR. WISNER R. TOWNSEND offered the following resolution, which was adopted:

*Resolved,* That the Secretary of the New York State Medical Association notify the treasurers of the various county medical associations that if dues are accepted for the year 1906 from members or candidates for membership such dues shall be returned in case the order for the amalgamation of the New York State Medical Association and the Medical Society of the State of New York shall be entered on or before January 1, 1906.

**President's Address.**—DR. J. RIDDLE GOFFE said that from every point of view the result of the year's work was a subject for congratulation and encouragement. It was a source of no little pride that in the face of the troublous times that had beset them they had not only been able to stand pat in their membership, but had actually increased it. Many of their members were also members of the County and State Medical Societies. This seemed to be a needless expense to have the payment of dues in both continued, and yet only a very few failed to pay their dues and continue their membership. At the last meeting a resolution was unanimously endorsed that it was the unalterable desire of the New York State Medical Association that harmony and good fellowship should prevail throughout the entire profession of the State, and to that end this association pledged itself to use its best endeavors to secure the union of the two State organizations until that much-desired end should have been accomplished. He said that the plan of campaign for the amalgamation of the two societies had been along two distinct and different lines. Knowing the generous and altruistic spirit that animated the association, and how thoroughly the members were endued with the conviction that in thorough and complete organization resided increased power for ennobling the profession, strengthening its dignity and influence, protecting it against its enemies, and advancing it to a higher plane of usefulness, he said he was convinced that any latent or active opposition lay in a misconception of the conditions of the amalgamation agreement and the practical working of the newly constituted society. To overcome these seeming misconceptions among the indifferent and actively opposed there was opened a wide and vigorous correspondence, with the hope of setting forth these apparently objectionable points in a more favorable light. This correspondence, supplemented by conferences at the district branch meetings, had, fortunately, been successful in allaying the apprehensions of many and arousing some to enthusiastic advocacy of amalgamation. A supreme effort was made to place all the acts of the association toward amalgamation on a strictly legal basis. To this end the council instructed the president to secure the best available legal talent in New York as associate counsel to their legal adviser, Mr. Lewis, and obtain from this combined talent a mode of procedure that would embrace all the requirements of the law and avoid any violence to vested rights. Dr. Goffe said that even at the last moment, although there had been some mutterings of opposition, he could not repress the hope that this vote in favor of amalgamation might be a unanimous one; that with flags joyfully flying at the masthead and themselves cheered with the thought that with whatever self-sacrifice might be necessary, they were keeping step with the march of progress and promoting the best interests of their beloved profession.

**Illness of Dr. Ferguson.**—DR. WISNER R. TOWNSEND said that members of the association would be pained to learn of the illness of Dr. Ferguson of Troy, and he moved that the association instruct the president to send a telegram to Dr. Ferguson, expressing the sympathy of the association and best wishes for his speedy recovery.

DR. JOSEPH D. BRYANT, in seconding the motion, with which he was in hearty sympathy, said that in a recent interview with Dr. Ferguson he had been assured of his intention of being present if possible and use what influence he could in bringing about the amalgamation of the two societies. The motion of Dr. Townsend was carried unanimously.

**Officers Elected.**—*President,* Dr. Allen A. Jones of Buffalo; *Vice-President,* Dr. H. Ernest Schmid of White Plains; *Treasurer,* Dr. Wm. G. LeBoutillier of New York; *Secretary,* Dr. Charles I. Redfield of Middletown; *Chairman Committee on Arrangements,* Dr. Frederic W. Loughran of New York; *Chairman Committee on Public Health,* Dr. A. A. Hubbell of Buffalo; *Chairman Committee on Legislation,* Dr. E. Eliot Harris of New York; *Chairman Committee on Publication,* Dr. Robert J. Carlisle of New York; *Chairman Committee on Library,* Dr. Alexander Lambert of New York; *Delegates to America Medical Association,* Drs. E. Eliot Harris of New York and J. W. Grosvenor of Buffalo; *Alternates,* Drs. Charles G. Stockton of Buffalo, George H. Reese of Cortland, John A. Fordyce of New York, and Wm. G. LeBoutillier of New York.

SECOND DAY—TUESDAY, OCTOBER 17.

The entire morning was taken up with the business of

the association with particular reference to the amendments to the By-Laws as a whole, which were unanimously adopted as read by Dr. Townsend.

**Amalgamation of the Medical Society of the State of New York and the New York State Medical Association.**—Dr. Wisner R. Townsend reviewed the work that had been done in furtherance of the object of amalgamation and moved that the resolution calling for it be adopted and that the balloting for it be proceeded with.

Dr. E. Eliot Harris, in seconding the motion, spoke warmly favoring the adoption of the resolution.

Dr. Joseph D. Bryant, as President of the Medical Society of the State of New York, said that he had worked hard for the amalgamation. Also that, at the suggestion of Dr. Ferguson, he had sent out 6,100 copies of the "Principles of Medical Ethics," so that every member in the State had received a copy. The result of the balloting showed, out of a total of 1,814 registered, 1,517 in favor of amalgamation, 2 opposed, and 295 not voting.

**Memorial to Dr. Baldwin.**—Dr. John Shrady read a memorial on the late Dr. Frederick A. Baldwin, treasurer of the association.

Dr. S. Suzuki, Surgeon-General of the Imperial Japanese Navy, was introduced by Dr. Goffe. Dr. Suzuki expressed his pleasure in being present, and for the honor they had bestowed upon him in asking him to sit with them during the proceedings.

**Reorganization of the Army Medical Department.**—Dr. Louis L. Seaman introduced a resolution, which was unanimously carried, that the New York State Medical Association respectfully petition Congress at its next session to reorganize the medical departments of the Army and Navy of the United States and place them upon the broad basis of that of the countries most advanced in military sanitation, to give the army medical department an independent transport system, to grant its officers power to enforce sanitary measures, and to create a personnel capable of caring for the ill and aged in the service; and also that Congress be petitioned to direct a graded course of study in sanitation and hygiene at both West Point and Annapolis.

**The Benefits of Organization.**—Dr. J. Riddle Goffe offered this as the President's Address and said that in every department of human endeavor the dominant note of the present day was organization. It was a basic principle of all progress and had its early inception in the idea of division of labor; in a wider sense it had its foundation in the very elements of nature itself and might be said to be the watchword of Creation. He spoke of what organization had done for countries and for the laboring classes; in all this great movement that had embraced every activity that had any vitality the medical profession had been a laggard; a new light had come and organization was the demand of the hour. In the words of William Morris, "To cease to fear our fellowmen and learn to depend upon them, to do away with competition and build up cooperation was our one necessity." In the old constitution making days of the colonial times medical societies were organized along the same lines as the national government; viz., county, district and state bodies, each dependent for its composition upon an assemblage for the next lower grade. Conspicuous in this movement were the medical societies of Connecticut, Massachusetts and Alabama. In these States the scheme worked successfully, but in obscurity. The New York State Medical Association had the distinction of having rediscovered this quiet little scheme, and in the reorganization of the New York State Medical Association at the time of its incorporation this plan was elaborated and adopted; it had not only been a lesson to our sister States, but also to the American Medical Association itself. The distinguishing features of this organization were that the County Association was the unit, that membership in it carried with it membership in the district and State associations, and through the latter to the national body. As society throughout the civilized world recognized the family as the unit and foundation upon which the whole structure rested, so the county organization was the unit upon which the whole superstructure rested. The intimate relations of the family circle cultivated forbearance, self-restraint, self-sacrifice, love and charity, as well as an intimate knowledge of each other's character, and these in turn beget unity, peace, and concord Members of the County Association were but children of a larger growth, where the same homely virtues need to be practised and cultivated. The County Association existed primarily for the dissemination of medical science and art, but the full benefit of this part of the work could not be obtained without eliminating the personal equation, and this could only be done when an intimate acquaintance existed. The program of a monthly meeting should always include a definite time for social intercourse. To know the pitfalls and errors that mar the successful making of a local society and prevent it from attaining the highest fulfillment of its mission was of inestimable value. Dr. Goffe quoted from Dr. Osler and from one of Conan Doyle's novels to illustrate the advantages of professional brethren living together in harmony and not allowing nonessentials and miserable trifles to mar the good fellowship and friendly intercourse that should exist between physicians. He spoke of the mutual benefits to be gained by the meeting together of old and young practitioners on a friendly basis. The scientific handling of disease was not the whole thing, by any means, and the young man would find much to learn from the old doctor in the sympathetic handling of the patient while at the same time he fought the disease. The scientific work fixed the intellectual status of the members. The discussions of the papers soon developed who had the observant eye, the keen ear, the delicate fingers and the educated touch. The well-conducted medical society represented a clearing house in which every physician in the district received his intellectual rating, and in which he found his professional assets and liabilities, as Dr. Osler had aptly expressed it. The aim of the society should be to see that every respectable physician was a member of the local society, and that every practitioner who was not respectable was bounced out of the profession. While the County Society might not make finished scholars of all its members, its influence was always for good. Through the Medical Directory and the State Medical Journal the association was made compact, the mutual interests and dependence of the constituent societies kept alive, and the organization as a whole made a ready instrument for defensive or aggressive action. He sincerely hoped that the newly constituted society would continue the directory. The reports of the various county meetings had stimulated commendable rivalry in the excellence of the programmes and the quality of their reports. The superiority of the Journal over the traditional volume of transactions would seem to need no argument. He referred to the effort being made to expose the evils of the so-called proprietary drugs. He thought he was not overstating the situation when he said that from the standpoint of the health of the community and the dignity and welfare of the profession the exploitation of quack nostrums was the greatest abuse of the present time. The running of a State medical journal required a properly selected editor with a reasonably remunerative salary. By combining the work of editor and secretary in the hands of a paid official, the work of both would be efficiently performed and no imposition practised upon anyone. There were now sixteen State medical societies which had journals. By these journals forming a combination against the advertisements of secret or proprietary medicines a great power for good could be exerted. Malpractice defense was a pertinent feature in their organization, and it had worked most satisfactorily. The work of the insurance companies along this line was worse than useless, because they were always working on a strictly business basis. A directory, a journal, and a malpractice defense were certainly tangible benefits and well worth the expense they

involved. He said that the principles of ethics needed no advocate; they stood as a masterpiece of diction, a model for every man in the profession to emulate.

**The Abrupt Onset of Typhoid Fever.**—Dr. Morris Manges read this paper. He said that especial stress had been laid upon the variations in the onset of typhoid fever recently, as if these irregular cases were a new feature. Greater improvements in the diagnostic methods, and especially the Widal reaction, had established the identity of a large number of cases which formerly escaped recognition, and for this reason were probably largely instrumental in spreading the disease. These irregular cases were far more frequent in children than in adults. The high mortality of these cases made their early recognition imperative. As regarded the frequency of this mode of onset, a careful study of the cases at Mount Sinai Hospital showed that it occurred in about ten per cent. of all cases. The recognition of the abrupt onset was not new, as it was described by Chomel in 1834. In studying these cases Widal noticed the very early occurrence of his reaction in this group, it being positive on the third to the sixth day, and he believed that the suddenness of the invasion was to be explained by the fact that the typhoid bacilli had "developed silently" in the organism. The bacilli might be unusually virulent or they might be associated with antecedent infections which had lessened the powers of resistance of the individual, or, on account of the presence of a mixed infection, had favored the rapid growth of the typhoid bacillus. He distinguished between those cases which were really abrupt and those which seemed to be abrupt but really were not so, as those cases of walking typhoid. Cases of abrupt onset might be ushered in, either with chill, single or repeated, severe pains in the abdomen, head, or other parts of the body, or virulent delirium; or they might act as cases of appendicitis, nephritis, pneumonia, pleurisy, grippe, etc. Some cases acted like diphtheria, or cases with marked hyperpyrexia, while another type were the hemorrhagic cases. He had seen a unique case in which the initial symptoms were a marked tachycardia and heart failure. Closely allied to the cases of abrupt onset were some of the cases of paratyphoid, the sudden onset of which brought this class of cases into close relationship with the group under discussion. Some abrupt meningeal typhoids resembled cerebrospinal meningitis. A simple leucocyte count usually served to make a differential diagnosis. A low count, from 3,000 to 5,000, is usually present in cases which developed as typhoid. The lumbar puncture gave additional diagnostic information. Clinically the cases might run an identical course for a number of days. The pneumotyphoid and pleurotyphoid cases were too well known to need further description. Another abrupt type was where the patient was able to give not alone the day upon which the disease began, but the exact hour. Another type of sudden onset was that marked by sudden high fever, which might or might not be associated with chills. In from twenty-four to thirty-six hours the temperature might reach 105 to 107° F., and the course reminded one of some severe poisoning rather than typhoid fever. Death usually occurred at the end of the first week, the patient seldom surviving beyond the second. These cases were rare. Dr. Manges had seen one case in which the temperature had risen to 111° F. shortly before death on the tenth day. The hemorrhagic form of typhoid was often ushered in with sudden onset, and ran a brief and rapidly fatal course. These cases were often mistaken for typhus fever. Malaria might be associated with the sudden onset of typhoid fever. As was brought out in the late Cuban war, malaria was apt to complicate the beginning or the end of the disease, but was not a factor of the disease in its fully developed stages. Chilliness or repeated small chills were extremely common, occurring in 23 per cent. of the cases at Mount Sinai Hospital. Repeated severe chills without any malarial affection might also occur. Sudden onset in the throat characterized a class of cases which was rather rare. Diphtheria might be associated with the sudden onset of the disease in some cases. Another type was characterized by high fever and nephritis. One case with these symptoms ran a continuous temperature for four weeks with delirium, and no explanation could be given beyond the nephritis and continuous fever. The Widal reaction was frequently sought, but did not appear until the temperature fell and the urine cleared up. The grippe type presented features of peculiar gravity as regarded diagnosis. He cited the case of a young man who apparently had a typical case of grippe from which he seemed to recover, when six days later he developed typhoid fever to which he succumbed from perforation. The general consensus of French opinion was that the antecedent attack of grippe had predisposed to typhoid. He could not absolutely agree with this view until further opportunity had been given to study the Widal reaction in the earlier attacks. The progress of the case, the roseola, the Widal reaction, etc., alone enabled one to differentiate these cases. The explanation of these cases as already given would not hold good in all cases. The explanation seemed to be in the rapid development of the organism within the body The rapid growth might be favored by a preexisting infection such as grippe, malaria, etc., or by other causes which have lessened the resisting power of the patient. In this class of cases a properly applied test for the Widal reaction should never be omitted, as the fact that the Widal reaction developed so early in cases of typhoid with abrupt onset lent particular value to this test in these cases.

Dr. Albert Kohn of New York said that any lesion beginning in the larynx, such as an ulceration, would have the symptoms referred there before referable to the abdomen; the so-called typhoidal appendicitis would have the symptoms referable to the appendix first. The site of the lesion had much to do with the suddenness of the onset. He said there were two predisposing factors. Many started with meningeal form with a previous history of headaches, and here the onset would be sudden. The presence of the roseola was uncertain, the enlargement of the spleen was uncertain, the tongue was not typical, but the pulse in the vast majority of the cases was slow. Any one symptom looked for was more or less doubtful. He believed the facial appearance of the patient would aid greatly in the diagnosis.

Dr. Charles G. Stockton of Buffalo said that the localization of these lesions was entirely conjectural, and that it was very difficult to say why in septicemia one occasionally found manifestations in a meningitis, again in the kidneys, again in the lungs. The same was true of influenza. But when typhoid selected deep organs one was apt to have a sudden onset, according to his observation.

Dr. Manges said that there certainly was something in the patient's look, and that they looked sicker than one would expect from a high temperature. He emphasized the value of the Widal reaction, and in an enormous experience with this reaction he had never been misled by the statement of the bacteriologist; a positive reaction meant a positive typhoid.

**Lumbago and Sciatica, Pseudorheumatism.**—Dr. James J. Walsh read this paper. He said there was probably no set of affections that were a source of more opprobrium and dissatisfaction to the modern practitioner than lumbago and sciatica. The chronic rheumatisms were extremely dissatisfying as regarded diagnosis and treatment. This was a field in which the quack had accomplished more than in any other field of practical medicine. This was a reason why it was increasingly difficult to prevent the osteopaths from obtaining legislative recognition. They had treated this class of patients more effectively than a number of general practitioners and specialists who had preceded them. One reason why the ordinary physician failed to benefit such cases was that the word rheumatism had become inextricably attached in his mind with the remedies that were usually applied, and was not directed

to other forms of treatment which might better serve the purpose of affording relief. Because lumbago and sciatica had been dubbed "rheumatic" it was taken for granted that the salicylates would surely do them good. The salicylates were excellent for the immediate relief of pain, but they should not be given to old people over long periods of time. They were inclined to affect the blood unfavorably, predisposing to anemia. Prof. Brouardell of Paris, in his experiments as to the effects of the salicylates on the organism at different ages, found that at the age of twenty years the salicylates began to be eliminated in the urine in about two hours, in a person of forty no trace of them could be found for almost twelve hours, and in a man of sixty-five they did not make their appearance until after twenty-four hours. At twenty years the elimination was complete in less than twenty-four hours; at forty, not until after forty-eight hours, and in old age there were traces of the salicylates after four days. This emphasized the necessity for care in the use of this drug, especially if there was renal insufficiency. As a matter of fact, lumbago and sciatica had, in most cases, very little of the aspect of rheumatic affections. They might be treated under two forms, the acute and chronic. Usually the acute occurred after exertion or when an uncomfortable position had been occupied for a long time. They might be described as sprain. Sometimes lumbago might result from chilling the lower portion of the back. This caused congestion in the muscles, disturbed the nutrition of the sheaths that must be kept smooth and healthy to perform their function; when the nutrition was lowered there was friction and consequently pain and hindrance to movement in these tissues. Such conditions were especially liable to occur if there were toxins in the blood likely to be irritant to delicate structures. Hence it was that persons suffering from tuberculosis were more likely to have neuralgia than others. Sir James Grant of Toronto had assured him that he sometimes succeeded in obtaining relief from very severe painful conditions in these parts by the insertion of ordinary steel needles. He attributed the pain to disturbed electrical conditions, and the small steel conductor provided an escape for the accumulated electricity. Acute puncture had proved to be a helpful remedy in many of these serious acute conditions. Affections in which toxic substances abounded in the blood were frequently complicated by affections of the nerves. The sciatic nerve was most likely to be affected. People who walked much might have their diabetic neuritis in their anterior tibial nerves, giving a characteristic toe drop that was almost typically alcoholic in origin. Alcoholic neuritis of the anterior tibial nerve might be accounted for by the fact that this, in persons of sedentary habits, was the most used nerve in the body, and consequently most subjected to the action of absorbed alcohol in the system. This same principle must be applied to all forms of sensory or motor disturbance. This was true in regard to sciatica and its connection with certain occupations. If the sciatic nerve was used more than others and a toxic condition was present, there would almost surely be disturbance of the muscles, causing reflex sensory disturbances. Where these troubles were due to overworked nerve, something could be accomplished by showing patients how to use their muscles with the least waste of nerve force. This had been accomplished very practically and on scientific principles by the Sloyd method of teaching workmen how to do their work hygienically. The main thing was not to consider these vague pains as rheumatic, but to recognize what was the trouble in each individual case and to try to correct it by means of direction, massage, change of occupation, hydrotherapy and other methods at our command. In not a few cases pains which seemed to be lumbago or sciatica were hysterical in character. In these cases the patients must be treated for their nervous condition.

**Some Experience with Apomorphine.**—Dr. George H. Peddle of Perry, N. Y., reported in detail two cases of alcoholism which he had treated with 1/20 grain doses of apomorphine with happy results. It was also of value in hysterical contortions or fits, in poisonings by strychnine, in insanities produced, for instance, by bromides, etc. Also in poisoning by the oil of tansy, delirium tremens, and poisoning of almost any nature accompanied by high arterial tension. A few cases were reported to show the wonderful effects he had obtained by the use of apomorphine.

**The Significance of Dysmenorrhea at Puberty, and Its Relation to Uterine Tumors.**—Dr. Frank DeWitt Reese of Cortland, N. Y., presented this communication, which was based partly on records of his cases kept over twenty years, from reading and from personal communication with certain well-known gynecologists. He said that all cases of uterine fibroids gave a history of severe pain, first manifesting itself at the menstrual period, and continued unless interrupted by pregnancy or some other agency. He said he had tried to discover the cause of uterine fibroids, but had failed. He had written to prominent gynecologists, asking them what they considered to be the cause of uterine fibroids. There seemed to be a paucity of statistics on this point, thus opening up a new field for investigation. The uterus, he said, must have something to do, and if pregnancy did not take place a fibroid was formed. He had two propositions to submit: First, was dysmenorrhea a symptom which indicated the presence of a fibroid at puberty? Second, can the exciting cause of dysmenorrhea be the exciting cause of the fibroids? His answers were based upon the histories occurring in his own practice and the statements of authorities. In his histories he learned that all his patients with fibroid tumors of the uterus had dysmenorrhea from puberty. He believed it was impossible for patients to have fibroid tumors of the uterus before puberty without having pain, and yet no actual symptoms would be produced prior to sexual activity. He was trying to establish his claim that the causes of dysmenorrhea were the exciting causes of fibroids. He believed the treatment of fibroid tumors of the uterus should be of a prophylactic nature, the treatment being primarily addressed to the preceding dysmenorrhea.

Dr. Mary Gage-Day of Kingston-on-Hudson said it was a serious thing for a girl to be partially or wholly disabled, from a few hours to days, in some cases each month; and only by getting a more thorough knowledge of the subject could we better present treatment. There were two classes of cases—first, those who had been great sufferers from the beginning of menstrual life, and, secondly, those who menstruated normally but once and, through ignorance, had committed some imprudence which had resulted in some inflammatory state of the pelvic viscera. The conditions interfering with the normal development of a girl were so numerous that it was a wonder that any developed into normal womanhood. Because girls did not die of dysmenorrhea there was no chance to make scientific study of this subject, and whether the relationship of dysmenorrhea at this period to uterine fibromata later in life was that of cause and effect, or whether the primary nodes of the neoplasm existed in the fetal structure, they were unable to tell. Most authorities stated that uterine fibromata did not exist prior to puberty, although Howard Kelly considered it probable that they did exist perhaps in microscopical size from fetal life. Cases were cited illustrating the strong heredity tendency there was in some families toward abnormal developments. Whatever our theories were concerning the etiology of these conditions, the practical question was, how were they going to treat these conditions who begin their menstrual life with such sufferings? Her remarks were then limited to the hygienic and medical management. There was no cure-all. The actual medical treatment she believed to be hot teas, hot applications, and rest in bed. If no relief followed this, then the necessity for a pelvic examination was explained and the conditions treated as found.

THIRD DAY—WEDNESDAY, OCTOBER 18.

**Test Feces; Their Value in the Recognition of Intestinal Disturbances Taking Their Origin in Other Parts of the Digestive Tract.**—Dr. HEINRICH STERN of New York said that not every disturbance of intestinal function originated in the intestines themselves, and that the stomach, liver, and pancreas were the organs which often caused intestinal disorder. After the administration of his test-regimen there always occurred some debris of connective tissue in the test feces. If the amount of such debris was large we might be convinced that gastric insufficiency was the root of the whole evil. Intestinal disorders of hepatic origin were of less frequent occurrence. Most intestinal affections caused by insufficient liver action were the direct consequence of disordered biliary secretion. When biliary difficulty stood at the bottom of the intestinal affection, the test feces presented a grayish color, and occurred in very large amounts. The sublimate test was negative, considerable masses of fat being excreted with them. Large amounts of fatty acids might be demonstrated in them, but no pathological amounts of other food residues. Intestinal disorders of pancreatic origin could only be recognized when the entire gland had degenerated. When there existed but a partial destruction of the pancreas, an eventual secondary intestinal disease could not be ascribed to it. The test feces, in case the entire pancreas was atrophied or otherwise degenerated, exhibited similar amounts of fat as the test feces of biliary obstruction. The test feces of both pathological states differed, however, in the following points: The feces in pancreatic disease was less copious than in biliary disturbance; they contained the biliary pigmentary substances; they exhibited large amounts of muscle debris and contained their fat very often in the form of neutral fat globules.

**What Organized Malpractice Defense Does for the Profession and the Public.**—Mr. JAMES TAYLOR LEWIS spoke of two directions in which the public was especially interested outside of the subject of scientific medicine and surgery, and these led directly to the improvement of the public health, and naturally were of interest to the profession itself. These two branches were the enforcement of medical laws prohibiting the illegal practice of medicine by quacks and charlatans, and the successful removal from the mind of the medical and surgical practitioner of the ever-present danger and threat of the dreaded malpractice suit, so called. From 1887 to 1905 there had been conducted in the State of New York, and especially in the County of New York, more or less continuous efforts against these non-medical persons with the hope of driving them from the State, and thus throwing about the public real medical protection against a class which was doing as much damage as disease or pestilence; but from his experience it had been proven beyond peradventure that to-day there existed in their midst as many, if not more, of this class of criminals as were found when the work was begun. This was due to two reasons; one was the support which this class of criminals received from the advertising columns of our daily papers, and the second was the inadequacy of the medical law with reference to the punishment of these law breakers. It had been thought that organized malpractice defense had originated in the minds of members of the State Medical Association. That might be so, but there had existed in the medical societies of England a similar defense proposition which had also been successfully carried on. At the time of the reorganization of the New York State Medical Association this subject was discussed by the speaker with Dr. E. Eliot Harris and Dr. Frederick Holme Wiggin. The question of means to carry on the same was of serious consideration, and it was thought that if one of the large insurance companies would undertake this defense, with their legal department fully equipped, it might prove a satisfactory plan; but after consultation with the attorneys and officers of these companies it was found that the expense would be too great, and that the policies issued by these companies would not be accepted by the entire membership of the association. At this time statistics showed that one doctor in 150, or every doctor once in 150 years, was sued for malpractice. Statistics, so far as they could be gathered at present, showed that in the past year one doctor in 275 was sued for malpractice. This showed something of the effect of persistent and organized defense of malpractice suits by a reputable medical organization. One of the most prominent surgeons in this city, who had given much time and study to the use of the *x*-ray, and who had furnished one of the hospitals in our city with the results of his labors and had purchased a full set of instruments and contributed them, was the first against whom an action was brought for burning with the *x*-ray. Even now protection from these rays was uncertain; yet the public was indebted to the medical profession for this great light; yet there were those who, under the advice of a shyster lawyer, were willing to prosecute, no matter how careful the surgeon might be. The reports showed that about 97 per cent. of so-called malpractice suits were brought for blackmail purely, and without any idea of whether there was a *bona fide* claim or not, and when reached for trial were abandoned. With the successful continuance of this work, this percentage would slowly increase, though there would, of course, remain a very small percentage of cases where there was a proper legal question to be decided by a court and facts to be decided by a jury. The legislation committee should consider the introduction of a bill in our State legislature compelling malpractice litigants to file security for costs when action was brought. This would cause the blackmailing variety to pause. The theory under which this defense was worked out was that if insurance companies could afford to pay counsel in various parts of the country, employ agents to secure defense insurance premiums, hire expensive offices, and pay large salaries to officers and then pay a large dividend to the stockholders when they would charge only $10 for the premium on a policy of defense, surely a great representative medical organization with all the conveniences of proper defense at hand should be able upon an economical basis to defend its members for a very small annual charge. The success of the defense and the enormous influence which it had exerted on the mind of the profession and of the public was due to the fact that it was purely a fighting defense. The public had come to know and shyster lawyers had been given to understand that no quarter was asked or given. It was understood that when the defense of a member was once undertaken by the association, it would be continued to the court of last resort, which was an extremely tiresome proceeding for the shyster lawyer to contemplate. The member, of course, understood that the association stood ready to uphold him if what he had done was proper and he had made the best use of an enlightened judgment. This was what the law required, and what the council of the State Medical Association had demanded. The success of this defense when the doctor felt that he had the support of his fraternity and of a great medical organization was bound not only to benefit the public, but with a few continuous years of this defense would stamp out once and for all one of the great stumbling blocks in the way of scientific medical and surgical experimentation, and would allow earnest study and practice within limits, to take the place of this ever-present fear in the mind of the medical practitioner of one of the greatest evils with which the medical profession had to deal. He referred to continuous effort, because occasional fits and starts in any movement did harm as well as good. People got the idea when a novelty was temporarily abandoned that it had been ill-advised or unfortunate. Now that amalgamation of the great medical organizations was assured, it was hoped that the final order of amalgamation would be entered speedily, and it was expected that the wisdom of malpractice defense by a medical organization had become sufficiently evident

and the benefits of such defense so forcibly settled in the minds of the medical profession of this State that the work would be continued without interruption under the auspices of the amalgamated society.

**Protection of the Water Supply.**—Dr. Thomas Darlington, Commissioner of Health of New York City, stated that a careful study of the conditions on the Croton Watershed and of the various other water supplies of the greater city, covering a period of many months, had convinced him of the necessity for the establishment of filtration plants. The watersheds of the city extended over a number of miles; those which supplied Manhattan and the Bronx covered over 360 square miles. Within such an area, where there were many inhabitants, the task of giving absolute protection from pollution was impossible. The problem was still further complicated because a part of the water supply came from the State of Connecticut, which was out of the jurisdiction of New York City and State. With the establishment of filtration plants it would be possible to guarantee pure water, even if the sources of the present supply were largely outside the jurisdiction of the City of New York. Filtration was no longer an experiment. A well-made sand filter would remove 99.5 per cent. of the bacteria from the water, besides most of the organic and inorganic materials suspended therein. It was an old but fallacious idea, Dr. Darlington said, that flowing water purified itself. Within a short distance of its source the impurities discoverable by chemical methods might be entirely lost; bacteriologically, or, rather, from a pathogenic standpoint, however, it did not change perceptibly. Where we had contamination from human excrement in the water, we might look for human diseases to follow. In connection with his remarks, Dr. Darlington showed a number of lantern slides of the Croton Watershed, with possible sources of contamination.

Ernst J. Lederle, Ph.D., said the death rate from typhoid fever in New York City was comparatively low—about 19 per 100,000—and had been steadily reduced from 1900 to 1905. Of 126 American cities, with a population of over 30,000, there were only twenty with a smaller death rate from typhoid fever than New York. The following were the typhoid death rates per 100,000 inhabitants of some of the principal cities in the United States: Pittsburg, 122; Philadelphia, 51; Cincinnati, 45; Baltimore, 35; St. Louis, 31; Boston, 26; New York, 19; Detroit, 18; Milwaukee, 18. The following sources of typhoid fever had to be taken into consideration in the study of the matter in New York: 1. Milk, which was at times infected at the dairy or in distribution to the consumer. 2. Shell fish, particularly oysters, which were freshened (fattened) in sewage polluted water. 3. Uncooked vegetables, such as lettuce, celery, etc., from farms fertilized with sewage or "night soil." 4. Imported cases. 5. Secondary infection. 6. Ice. 7. Infected food due to flies carrying infection from privy vaults to the kitchen or dining room. 8. Domestic water supply. 9 Public water supply. To a large extent, typhoid fever came from impure water. In the city of New York, a small percentage of typhoid cases had come from oysters that had been contaminated; other cases had been carried in from the outside; still others had come from milk contaminated by some local water supply. During the past five years, the number of deaths from typhoid fever in New York City were as follows: 1900, 718; 1901, 727; 1902, 765; 1903, 653; 1904, 661. Dr. Lederle said that while it did not appear from the above figures that the water supply of this city was in a serious condition, he thought all would agree that every precaution should be taken to insure its purity, and in order to secure this, the installation of an efficient filtration plant was essential.

**Typhoid; What Are We Going to Do About It?**—Mr. Samuel Hopkins Adams discussed this phase of the subject. He stated that within a few years a number of our American cities had awakened to the astonishing discovery that typhoid fever was expensive. Cleveland found that the prevalence of the disease was giving the city a bad name and hurting business. Chicago discovered that the daily boiling of germs occupied the kitchen range to the exclusion of more appetizing cookery. Pittsburg, every time a new wave of industrial prosperity swept over it, perceived with dismay its resultant influx of population, which had not been brought up on sewage, passing swiftly from the water faucet to the hospital to an extent that crippled the commercial output. Even Philadelphia decided that, on the whole, assorted germs were too dear a diet. These and other cities, each in its own way, had set about getting a better water supply, and all indications pointed to the fact that in a few years the principal cities of the United States would be furnishing to their citizens water that was fit to drink. Ithaca now had its filtration plant. The lesson was learned at a terrible price, yet that was the price which most cities must pay. In the cause of pure water, public opinion, excepting when incited by terror or an epidemic, had to be stimulated artificially, so to speak. Seeing was believing, to the general mind. Nothing looked so clean as water, and the bad was often as clean as the good. Disease-bearing organisms, unfortunately, were not impressive to the lay view, even through a powerful microscope. If physicians, whose noblest work was the education of the public in the science of right and clean living, could put in provable form what they knew to be true concerning the relation between bad water and disease, the problem would be half solved.

**Protection of the Milk Supply.**—Dr. Walter Bensel of New York read a paper on this subject. He stated that the statistics of New York City showed that children under five years of age constituted about one-third and infants under one year about one-sixth of all deaths, and that a large proportion of these infant deaths was due to intestinal diseases. When we considered that cows' milk in some form was used during a considerable part of almost every child's life, and that, owing to the ignorance or carelessness of the larger number of milk producers, milk was notoriously filthy, we at once realized the importance of the enforcement of most stringent regulations concerning its production, transportation, and sale. The city of New York was supplied with about a million and a half quarts of milk daily, of which about two hundred thousand quarts were produced from dairies within the city limits. Handling this enormous quantity of milk were some 450 creameries and about 9,000 dairies. To inspect those creameries and dairies, the Department of Health employed two inspectors, more being unavailable through a lack of appropriation. Nevertheless, an enormous amount of work had been done. A large proportion of the creameries had been visited once or twice, and most of the bad conditions therein had been corrected, but the dairies remained as yet practically untouched. According to the Sanitary Code, milk was adulterated when it contained more than 88 per cent. of water, when it contained less than 12 per cent. of solids, when it contained less than 3 per cent. of fats, when it was drawn from animals within fifteen days before or five days after parturition, when it was drawn from animals fed on distillery waste, or any substance in a state of fermentation or putrefaction, or any unwholesome food; when it was drawn from cows kept in a crowded or unhealthy condition, when any part of its cream had been removed, when any foreign substance whatever was added to it, and, finally, when it was at a higher temperature than 50 degrees Fahrenheit. In connection with his paper, Dr. Bensel showed a number of lantern slide views of unsanitary cow sheds and creameries in New York and vicinity.

**The Acid Toxemia of Pregnancy.**—Dr. Henry McMahon Painter of New York read a paper with this title, in which he discussed the various theories of the subject.

**The Pathology of Eclampsia.**—Dr. James Ewing made some remarks, which he illustrated by means of lantern slides, of liver sections. He stated that about a year ago he gave a presentation of this subject before the New York

Obstetrical Society, and his further investigations had only tended to strengthen his belief that the three clinical manifestations of pregnancy, namely, eclampsia, pernicious vomiting and acute yellow atrophy, were essentially one and the same disease, although he did not mean to imply by this that they were similar in all respects. During the past eighteen months, Dr. Ewing said, he had made a fairly extensive study of the features of the urine in the toxemias pregnancy, including those of the non-convulsive type; some 150 specimens of urine had been examined. The findings of such examinations, he said, were only significant when the entire twenty-four-hour specimen was secured, and when the diet of the patient was exactly known. His investigations had shown that the percentages of urea-nitrogen and ammonia-nitrogen were very variable, and that the presence of leucin and tyrosin in considerable quantity in the urine was a much more reliable clinical indication of toxemia and its severity.

**The Treatment of Hyperemesis Gravidarum.**—Dr. William S. Stone of New York City stated that the treatment presented in this paper was based upon the assumption that the essential etiological factor was a toxemia, manifested by more or less severe metabolic disturbances, in which the liver, in the severest cases, at least, showed pathological changes that were readily demonstrable and were known to be the lesions in other diseases of well-recognized toxemic origin. This assumption was applied to both the mild and the severe types. The treatment, considered specifically, should consist of: 1. Rest in bed, absolute in most instances, at least for a few days; 2. exclusion of all visitors, even members of the family in severe cases; 3. a milk or broth diet, or absolute withdrawal of all food by the stomach in severe cases, but a liberal allowance of water; 4. catharsis at the beginning of treatment with calomel and salines, the latter sometimes to be repeated; 5. colonic irrigations with normal saline solution, or rectal injections of the same; intravenous infusions in the severest types; 6. nutrient enemata; 7. the administration of a few doses of opium, either hypodermically or by rectum. The writer considered the opium a valuable adjunct, and did not think that the beneficial results following its use offered any more argument against the toxic origin of the disease than did the good results of its use in other toxic conditions. In the treatment of the severe cases, particularly those of the acute or fulminating type, the additional evidence furnished by the complete chemical examination of the urine would give the most accurate knowledge of the gravity of the condition, although as yet the appearance of no single pathological constituent could be said to furnish an infallible guide. The choice of method in terminating the pregnancy might also be of the greatest importance. Rapid dilatation and emptying the uterus under a general anesthetic was a serious operation in these cases, and should not always be attempted, because the shock might be the determining factor in a fatal result. If it seemed necessary to resort to anesthesia, the writer advised the use of ether instead of chloroform, because evidence was accumulating that chloroform was particularly dangerous in the presence of marked disturbances of metabolism.

**The Prevention and Treatment of Eclampsia.**—Dr. Bernard Cohen of Buffalo stated that every man whose practice was such that he might be called upon to attend obstetrical cases should have in mind a definite outline of the treatment he was to pursue should he meet a case of eclampsia, no matter what theory he might hold as to its causation. The clinical course of the treatment for eclampsia was now fairly well defined, and was governed by certain well-established principles which would prevail until a more exact knowledge of this obscure disease required their modification. The preventive treatment was by far the most important, as it was by close observation of the patient during pregnancy and the consequent recognition of early symptoms that, in the majority of cases, we were able to ward off the attack entirely. The speaker said his experience did not warrant his saying that eclampsia was a disease that came on without any warning, and that many times, seeing the premonitory symptoms, he had been able to anticipate the attack and prevent its occurrence. In every case of eclampsia the premonitory symptoms were usually recognizable in time to prevent the fits. Immediate treatment should be given upon their recognition, but should the too rapid formation of poison prevent that treatment, we could at least interfere early enough to save mother and child. The speaker, after emphasizing the importance of preventive measures, discussed the medical and operative treatment of eclampsia. In regard to the latter he said that if labor had not started and the cervix was hard and unyielding, and the woman in desperate condition, he would advise Cesarian section by the abdominal route. In all of his cases the women were at term, or nearly so, and he was able, by the use of the graduated steel dilators and manual dilatation, after the methods of Harris and Edgar, to dilate the cervix. As soon as it was effaced he was enabled to apply the forceps or do a version and extract the child. This he regarded as the best method. It took considerable time, but destruction of tissue and sepsis were avoided.

**The Present Status of Vaginal Cesarean Section.**—Dr. M. Stamm of Fremont, Ohio, read this paper. He said it was now about ten years since Dührssen, of Berlin, brought this operation before the medical profession, and theoretically laid down its rules and indications, which seemed to have suffered very little change by time and experience. At first a number of theoretical objections were raised against this operation, and the profession was slow in giving it a practical test, but with increased experience those objections had been gradually removed. The purpose of vaginal cesarean section was to empty a pregnant uterus at once through the vaginal route by an anterior or posterior incision, or both combined, into the cervix and lower segment of the uterus without opening the peritoneal cavity in cases where the cervix was totally or partially closed, or where there was absence of pain or any effort on the part of the uterus to expel the fetus in due time. Dührssen, in his earlier publications, laid down the following indications: (1) Abnormal conditions of the cervix and lower segment of the uterus—carcinoma, myoma, rigidity or stenosis of the cervix, and partial pouchlike distension of the lower uterine portion. (2) Dangerous conditions of the mother which might be removed or relieved by promptly emptying the uterus—affections of the heart, lungs, or kidneys. (3) Conditions of the mother where death was imminent and could be foreseen. The speaker said that since his first publication on this subject (*American Journal of Obstetrics*, November, 1903) the operation had been done about eighteen times in this country, in most cases for eclampsia, which furnished the chief indication for it.

The subject of the toxemias of pregnancy was further discussed by Drs. J. Whitridge Williams of Baltimore, J. Clifton Edgar, Joseph Brown Cooke, David P. Austin, and James J. Walsh of New York.

**Resections of the Bladder in Rebellious Cystitis.**—Dr. Howard A. Kelly of Baltimore read this paper, and reported in detail a number of such cases coming under his care. He urged that many cases of advanced vesical inflammation, even of a tubercular character, which had heretofore been counted hopeless, were amenable to surgical treatment, even when it was necessary to go to the extent of excising one-half or two-thirds of the bladder. When the kidney was involved, that organ had to be attended to first, if the disease was extensive, and afterwards if the bladder infection was mild. A large percentage of these cases, probably eighty or ninety per cent., were associated with tuberculosis of the upper urinary tract. That should be relieved first. If there was a large, thickened tubercular ureter, it had to come out; and the time of its removal was also a good time for the excision of any periorificial or periureteral tubercular cystitis. This could be

done by the extraperitoneal route above in either man or woman. When the kidney was affected he thought it best to do the renal and ureteral operations alone at the first sitting, and then, if the vesical disease was at all extensive, to drain the bladder and excise the diseased areas later. If, however, the patient was not too stout, and was in good condition, all the operations might be done at one sitting. The fact should not be lost sight of, Dr. Kelly said, that in many instances bladders which had seemed to be badly affected at the time a nephrotomy or a nephrectomy was done had recovered spontaneously after the operation.

Dr. Kelly's paper was discussed by Drs. Hiram N. Vineberg, Hermann J. Boldt, and A. Ernest Gallant.

*(To be continued.)*

## MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

*Fifty-fifth Annual Meeting, Held at Scranton, September 26, 27, and 28, 1905.*

(Special Report to the MEDICAL RECORD.)

*(Continued from page 644.)*

Dr. RANDALL of Philadelphia said that while it was easy to think that mastoiditis was more easily diagnosed than formerly, it must be remembered that increased population and epidemics of influenza were factors in the increased number of cases recorded.

Dr. KATE W. BALDWIN of Philadelphia said that in all cases of septic conditions of the nose and throat the teeth should be examined, and she cited a case of a person of thirty-eight years with an unerupted wisdom tooth which had caused mastoid abscess.

Dr. J. H. MCKEE of Philadelphia, referring to the importance of examining the ear when cerebral symptoms were suspected, thought it far better to adopt the plan of Dr. Morse in the Boston City Hospital of making the examination of the ear a part of the routine examination of the child. Many obscure cases were cleared up in this manner. The subject of adenoids he thought an important consideration, and said he had yet to see a case of pneumonia, middle-ear disease, or typhoid fever in a child with middle-ear disease in which there was not sufficient adenoid tissue to be considered pathological. The importance of lumbar puncture in the presence of cerebellar complications of middle-ear disease he thought also should be remembered.

**A Plea for the Early Recognition and Immediate Treatment in Disease of the Accessory Sinuses of the Nose.**—Dr. W. G. B. HARLAND of Philadelphia read this paper. He said that the sinuses in the bone surrounding the nasal fossæ might be divided into (1) those emptying into the nose under the middle turbinated bodies, and (2) those emptying above the middle turbinated bodies. Cases were given illusetrative of sinusitis as ordinarily met with. The diagnosis of sinus disease was founded upon discharge, pain, and tenderness, condition of the teeth; disturbances of olfaction, appearance of the middle turbinate and of the outer wall of the nasal fossæ, transillumination, and skiagraphs. Treatment was best carried out by having the patient in bed, unloading the bowel, giving phenacetin, quinine, and atropine in acute cases. Free drainage should be promoted by the use of cocaine, adrenalin, and alkaline wash

Dr. PYFER of Norristown said the general practitioner did not realize that in every case of cold the sinuses were involved, and that the degree of headache confirmed the amount of sinus involvement. If sinus involvement was suspected, in addition to the internal medication he would prescribe the use of a spray of adrenalin and cocaine followed by an alkaline solution.

Dr. RANDALL of Philadelphia spoke in strong terms against the use of cocaine. While he acknowledged its value in the hands of a careful surgeon, he used it sparingly, and prescribed it never. In the antrum cases the pain being so habitually about the first and second molar, he thought the nasal and sinus involvement was apt to be overlooked.

**Teaching the Deaf Child to Hear.**—Dr. G. HUDSON MAKUEN of Philadelphia read this paper and referred to cases reported in the beginning of the last century by Itard and Toynbee of marked improvement in the hearing of deaf persons as a result of so-called aural gymnastics. Urbantschitsch found the use of musical instruments to be of value in diagnosis, and in one of Dr. Makuen's cases the piano furnished the only sound to which any response was given. His own practice was to begin the exercises with sounds similar to those of which the patient had shown some appreciation, and then gradually take up the sounds of the human voice. The following were the author's conclusions: (1) The hearing of the deaf child might be greatly improved by the systematic use of aural gymnastics; (2) the speaking voice used in close approximation to the ear was the most effective form of aural gymnastics for children; (3) the training of speech should be carried on simultaneously with the hearing exercises; (4) the degree of success attained would depend largely upon the patience and skill of the teacher.

Dr. EDWARD B. DENCH of New York said that Dr. Makuen's conclusions were the same as his own, observed in a limited number of cases. He had carried out the system of instruction by the use of the voice, and had been gratified at the results. In chronic nonsuppurating cases with progressive loss of hearing he had also found the results to be good.

Dr. Makuen in closing said that the results obtained in teaching children were better than in teaching adults, because in the case of children the hearing power had never been developed and there was simply the task of developing the child's appreciation of hearing. A child with a considerable amount of hearing power would appear oftentimes to be quite deaf.

**Address in Hygiene and State Medicine.**—Dr. G. W. WAGONER of Johnstown delivered this address. He said that sanitary work to be effective must be backed up by an authority, either assumed or delegated, that is absolute as to the work to be accomplished; the people must believe that it is necessary and have faith in the competency of those who undertake the work. The work of the State Board of Health following the Johnstown flood was referred to as an illustration of the enormous value of sanitary knowledge to a community when intelligently applied. He questioned whether the law "Creating a Department of Health, and Defining Its Powers and Duties," recently passed by the Pennsylvania Legislature was consistent in all its features. By this law the office of the Commissioner of Health was created with unlimited powers, and though the Act also created an Advisory Board, this Board was required to meet only "on the call of the Commissioner of Health," and was empowered only "to advise the Commissioner on such matters as he may bring before it."

**Protective Inoculations Against Typhoid Fever.**—Dr. D. H. BERGEY of Philadelphia said that the value of protective inoculations could be determined only by carefully comparing the health of the inoculated as compared with the health of uninoculated persons living under the same conditions. It was observed that the reduction in the incidence of typhoid fever among those inoculated by the Wright method varied greatly in different bodies of troops and also in regard to the number of injections made. In some instances the incidence was reduced one-half, while in others there was a six-fold to a twenty-eight-fold reduction. The case mortality among the inoculated as compared with the uninoculated has been reduced more than 50 per cent. While the method was of value, Dr. Bergey maintained that there should be no less energy used in eradicating all known sources of infection by the well-established means known to sanitarians

**Pain of Obscure Origin Simulating Neuritis, Neuralgia, or Organic Lesions.**—Dr. JOHN H. MUSSER described sev-

eral cases illustrative of the title of his paper, and further stated that in the elucidation of such cases thorough study must be made of the nerve itself, especially of the spinal cord, of the sensory and motor phenomena, and of reflexes of all kinds. In the cases described the usual phenomena of neuralgia were absent. After an exclusion of all central lesions there must be considered all possible lesions that may occur along the course of the nerve trunk, and in this connection the anatomical conditions must be recognized. Bony, vascular, and muscular lesions must be excluded or considered before a definite diagnosis could be established. Even with the study of such possible lesions conclusions could often not be reached as to the nature of the pain without a more careful consideration of the general phenomena attendant upon the case. From Dr. Musser's observation of cases he concluded that the physician should not at once decide that pain was of neuralgic or neuritic origin alone and be satisfied with the diagnosis, that he must look very carefully into the cause of pain and general phenomena, and that he must not rely too much upon sedative drugs.

**Report of a Case of Malignant Lymphoma with Autopsy, and a Brief Consideration of Splenic Anemia.**—Dr. J. A. Lichty of Pittsburg, reported the case of a patient, aged sixty-seven, who had been sick two years. There was primary enlargement of the spleen, absence of leucocytosis, gradual decrease of leucocytes, anemia, comparatively large number of erythrocytes, presence of pigmentation and of subcutaneous hemorrhages, absence of enlargement of lymphatic glands, no history of malaria, leukemia, syphilis, or cirrhosis of the liver. In the course of the disease there occurred enlargement of the liver and ascites. A diagnosis of splenic anemia was made. At autopsy there was found a great infiltration of lymphoid cells in the liver and the spleen, and the lymph glands about the celiac axis were enlarged. He concluded that the diagnosis of splenic anemia should be made with great reservation, and that it was more than likely that at present it was made too often.

Dr. P. Y. Eisenberg of Norristown regarded the case as one of those of blood disease whose etiology is not understood, whose prognosis is well understood to proceed progressively to a fatal termination, and whose treatment is very uncertain.

**Chronic Rheumatism.**—Dr. Charles W. Painter of Boston said that the basis of classification of the chronic rheumatisms used in the paper was to be found in a study of the etiology, the clinical course and phenomena, and the pathology of the disease. A plea was made for the clinician and the pathologist to work together, and it was urged that the pathology of the dissecting room and the autopsy table should seldom be allowed to color one's opinions of the diseases in question. Studied in this way he divided chronic rheumatism into three groups: In the first which seemed to be associated with some infective organism, the joint manifestations were more or less rapid in their development and acute in their character, and were accompanied by constitutional symptoms characteristic of an infection. The external lesions were quite significant of an inflammatory process. The second group, called atrophic because of its physical characteristics, was not inflammatory, either in its onset or progress, and seemed to be associated with some disturbance in the metabolism of the body. It was a disease more common in women and in young adult life and was very frequently associated with nervous shocks and mental worries of one sort and another Pathologically, the lesions were in the cartilage and bone as well as in the soft parts, thus differing from lesions in the infectious type, where they were very rarely situated in bone and cartilage unless the infection was very severe. The third group was called the hypertrophic because of the physical characteristics To this group belonged Heberden's nodes, morbus coxæ senilis, and other lesions of the same character occurring in the spine, the knee, the elbow, etc., for which there were no specific names. These lesions were characterized by an hypertrophy of cartilage about the joint lines and subsequently a true bone formation, which was permanent and gave rise to mechanical disturbance more than to any constitutional disability, though there was doubtless something of the latter somewhere concerned. Dr. Painter did not claim that this was an entirely satisfying method of classification, but it was a working hypothesis which would be found useful in solving some of the troublesome problems of the general practitioner, and would help lift from the profession the necessity for indiscriminately prescribing the salicylates for the interior and the oil of wintergreen for the exterior, and for telling the patient and his friends that his symptoms were the result of chronic rheumatism and there was nothing more to do.

Dr. James J. Walsh of New York City thought it particularly important to emphasize the necessity for individualization of patients, and to recognize the fact that under this group of chronic rheumatism there were a number of diseases which only when separated could be benefited by medicine. "Rheumatism," he said, "is a beautifully large word, and may include almost everything under the sun." Automatically with the thought of "rheumatism" to the physician come the salicylates. Referring to occupation neuroses Dr. Walsh asserted that there was not a single occupation in which a person did an habitual motion which would not cause pain around the joints associated with that motion. A change in the barometer would cause a pain in a tooth if it happened to be bad, and a pain in the arm if it was overworked, and this pain, he said, was not so different from that which was called rheumatism. All of these cases he said could be aided by ascertaining and dealing with the cause.

Dr. DeForest Willard thought it the bane of the medical profession to call pains rheumatism without making any diagnosis whatsoever as to the cause of the symptoms. He had seen cases which had been allowed to go on to bone destruction still treated for rheumatism.

**The Diagnostic Value of Blood Cultures.**—Dr. D. L. Edsall of Philadelphia, from the standpoint of the clinician, pointed out certain groups of cases in which blood cultures were of value, and referred to a series of cases of his own in which they were of value. The kind of cases in which the cultures were likely to be of value was that of bacterial infection in which bacteria got freely into the blood, and bacteria of the kind easily cultivated upon ordinary media. Dr. Edsall cited a mastoid case in which the ear specialist did not think there was sufficient evidence of mastoid disease, in which there was obtained a positive culture of a colon-like bacillus. In a series of gynecological and obstetrical cases mentioned by courtesy of Drs. Hirst and Evans, a local source of infection could not be found, but blood cultures were obtained and operation revealed abscess in the walls of the uterus. Dr. Edsall believed the method one of the most important means of investigation open to the profession

**Some Color Comparisons in Medicine.**—Dr. Henry F. Wetherill of Philadelphia read this paper, which was based upon the results of researches made on color scales for practically determining the percentage of hemoglobin. He showed an improved hemoglobin scale called the antemortem blood color scale. This was a practical improvement upon other hemoglobinometers, because it gave the true percentage of hemoglobin. Judgments of any color might be made between the 10 per cent. colors of the scale.

THIRD DAY—THURSDAY, SEPTEMBER 28.

**The Trend in Psychiatry.**—Dr. F. E. Mayer of Pittsburg delivered the Address in Neurology, in which he discussed the limitations of psychology and biology in relation to clinical psychiatry. Mental diseases, he said, should be regarded as a part of general medicine.

**Insanity in the Aged.**—Dr. Charles W. Burr of Philadelphia read this paper, speaking of the difficulty of determining the mental condition of the aged, because there was no dividing line between normal and pathological

senility. The best rule to follow, he said, was to discover whether the man knew what he wished to do, was competent to recognize the duty he owed toward his relatives, and was not swayed by momentary passion or delusions. Reference was made also to the frequency of acute mania and melancholia in old age, in which the outlook as to cure was almost as good as in early life. While it was true that physical and mental old age ran along together, yet the saying that a man was as old as his arteries, he believed was not true in every case. He said there were a certain number of people who became prematurely senile while the physical organism remained in fairly good condition. In the consideration of postparalytic insanity he thought it was perfectly possible for an old man after an ordinary hemiplegia to remain in fit mental condition to take care of himself; but that if there were also sensory aphasia or diffuse arterial disease, there would surely be more or less dementia. Apoplexies in old people, he said, were occasionally ushered in with a period of excitement.

Dr. Hugh Meredith of Danville thought Dr. Burr's paper of value to the whole medical profession, particularly because the insane patient came first under the observation of the general physician long before he was seen by the alienist.

**The Recognition of Hysterical Symptoms from Organic Symptoms.**—Dr. Theodore H. Weisenburg of Philadelphia in this paper reported cases showing the similarity of symptoms in hysterical and in organic disease, and pointed out the difficulties in diagnosis.

**Brain Abscess with Exophthalmos and Blindness.**—Dr. Edward B. Heckel of Pittsburg read this paper. He said that an interrogation point should be placed after the word "abscess" in the title of his paper, because the autopsy proved that it was not an abscess. The condition was one suddenly developed in a young married woman twenty-two years of age, whose previous history had been negative, except that upon close examination she admitted that she had suspected herself to be pregnant and had been persuaded to take some patent preparation, with the object of producing an abortion. The condition which attracted most attention was the sudden exophthalmos and blindness, which was complete within a few hours. Curettage showed no signs of a previous pregnancy. A typical septic temperature zigzagged between 105° and 99°. In addition to the exophthalmos, hemorrhages appeared in both anterior chambers. Death occurred eight days after the appearance of the exophthalmos. At no time had the patient complained of headache until the day previous to death. Streptococci were found, but no abscess formation in any part of the body. In the left frontal lobe there was a cavity about the size of a hen's egg, apparently filled with purulent fluid, but which was demonstrated to be a clot. There was no limiting membrane, but the cavity was studded with small millet seed granulations, so that even after the thorough autopsy a positive diagnosis was doubtful.

**The Clinical Examination of the Feces.**—Dr. J. Dutton Steele of Philadelphia said the method employed was that of Adolph Schmidt with a few modifications. This so-called functional examination of the stool had its limitations when used as a method of diagnosis; but it was of very great value in studying the digestibility of various food stuffs, in order to determine the proper diet in any given case. This was shown in a case from Dr. Musser's wards in the University Hospital, when a young farmer, aged twenty-three, was admitted with a history of chronic diarrhea, loss of weight, and abdominal pain. A test diet revealed almost no power to digest muscle fiber. His gastric function was normal, and the diarrhea was apparently due to an enteritis secondary to undigested muscle proteid. Upon stopping the meat diet the diarrhea promptly ceased. The starches and fats of his diet were then increased until the examination of the stools showed that the limit of each had been reached. Under this treatment the symptoms of enteritis subsided, and the patient gained twenty-eight pounds in a month. Dr. Steele stated that the method was simple and easy to carry out, and that it bade fair to be an accurate means of watching the power of the gastrointestinal tract to digest certain food, and hence would be of great use therapeutically, and, in a general way, of considerable value diagnostically.

Dr. Lichty inquired whether, in determining the length of time required for the food to pass through the gastrointestinal tract, there was any necessity for taking into consideration a dilated or prolapsed stomach, and, if so, how the figures would be modified. The point which most impressed him was the finding of mucus in the stools; and he thought the method should be put upon the same basis as that of gastric analysis.

Dr. Steele replied that he could not give any data relative to the question of Dr. Lichty.

**Scopolamine Hydrobromide.**—Dr. John V. Shoemaker of Philadelphia read a paper upon this drug which, he said, although it had recently attained much vogue, was not really a new remedy, as it was described in his book on therapeutics ten years ago. It was, however, introduced into the United States Pharmacopeia only in the last revision, in which it was stated to be identical with hyoscine hydrobromide. The drug was very powerful, and caution was urged in its use, the speaker having seen marked toxic effects from the one-hundredth of a grain.

**Diaphragmatic Hernia with Complete Extrusion of Stomach and Spleen.**—Dr. J. Bruce McCreary of Shippensburg presented this paper, detailing the history of the case: that of a man of twenty-two years, who fell in collapse after having run a foot race. His usual health was not recovered until the end of two years, when he still, however, experienced a feeling of pressure in the spleen, and chronic diarrhea was present in varying degrees for six years. Eight years after the first injury he was thrown from a carriage and had a return of the same symptoms. Three months later he had enormous internal hemorrhage. For three years the hemorrhages continued at intervals. A diagnosis of diaphragmatic hernia with partial extrusion of stomach, dislocation of heart, and pneumogastric fistula was made by Dr. McCreary and verified at the autopsy. During the illness of the patient relief from the extreme pain was given for a year by stomach lavage. By keeping the stomach clean the generation of gases had been prevented.

*(To be continued.)*

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held October 5, 1905.*

The President, Charles L. Dana, M.D., in the Chair.

**Is Paralysis Agitans Caused by Defective Secretion or Atrophy of the Parathyroid Glandules?**—Dr. William N. Berkely read this paper. He said that the glandules were generally four in number, and in man they were in close proximity to the thyroid, two being normally present on each side, one above the other, behind the rear border of each lateral thyroid lobe. They varied in size from that of a grain of wheat to that of a grain of maize. They were soft, yellowish brown, and were covered with a thin fibrous capsule. They were hard to find. The precise physiology of the gland was unknown. Did disorder or atrophy of the parathyroid glands cause a recognizable disease as Addison's or myxedema? If so, could the disease be relieved or cured by the administration of a properly prepared gland or gland extract? His own contribution to the question, obviously a difficult one, was that atrophy or insufficiency of the parathyroid glands was perhaps the cause of paralysis agitans. The following considerations were offered: 1. In studying slowly dying parathyroidectomized rabbits he was struck with the fact that the symptoms might be viewed as much more suggestive of paralysis agitans than of any other at that time commonly considered in the same connection. 2. Dana as long ago as 1893 suggested paralysis

agitans as being due to a "microbic or hemoral toxin" circulating in the blood, and having an especial affinity for certain areas in the spinal cord and medulla. The same opinion—that the disease was an endogenous toxemia—had been expressed by others, and some of the writers had suggested the thyroid gland as being the organ at fault. 3. During the past year he had found opportunity to administer a physiologically tested gland to eleven cases of shaking palsy in all grades of advancement, and he summarized the results. A case of Dr. Hunt's was some six weeks later reported negative. One of Dr. Dana's was much benefited. Of three cases of Dr. Smith's two reported considerably improved. A very advanced case of Dr. Taylor's was distinctly benefited. A case of long standing in Dr. Grinnen's care was improved. Dr. Peterson's and Dr. Janeway's cases, two in number, were improved. Dr. Kingman's and two of his own were greatly improved. All the patients remarked upon the curious increase in courage, comfort, and mental energy while taking the remedy. In summing up his therapeutic results he said that the remedy had been more or less fairly tried in eleven cases, and of these nine were greatly helped. 4. He said it had been noted in the recent medical literature that in autopsies on exophthalmic goiter the parathyroids had been several times reported unaltered. These and other facts, so far as they went, seemed to indicate that the parathyroids had no causal relation to either myxedema or Graves' disease. At the same time, there had been lately reported cases of concurrent Parkinson's disease and myxedema, and concurrent Parkinson's disease and Graves' disease, the symptoms being characteristic and the diagnosis unquestioned. Unfortunately at several autopsies the parathyroids were not examined. 5. The final disposal of his proposition he said hung upon autopsy findings.

Dr. J. Ramsey Hunt said that the case of the man referred to in the paper should be excluded from any serious consideration. It was one of moderate advancement, and he had been seen but once or twice after the administration of the capsules. There was no amelioration of the symptoms. With regard to parathyroids and Basedow's disease he said he had examined one such a case, a very severe one; the patient died suddenly with all the symptoms of Basedow's disease. The gland was removed by Dr. Rogers and examined by Dr. Ferguson, but the examination was negative in its results.

Dr. Jeremiah Sweetser Ferguson said that he had been studying the parathyroids with Dr. Rogers for some months now, and they had practically come to the same conclusions, *i.e.* that the glands were so extremely variable in their location, number, and appearances, that it was almost impossible to base any definite physiological or pathological deductions upon any findings which might be made unless those findings were verified by a careful microscopical examination. He presented a little résumé that he had made showing the number of times the parathyroids had been found in the pieces of tissue that had been removed by Dr Rogers for examination with the idea that they might prove to be parathyroids. The dissections had been carefully carried out. The observations so far made had been chiefly upon man, but glands from the dog, horse, and rabbit had been examined as well. Dr. Rogers dissected 189 pieces of tissue at various autopsies, four or five pieces being the average taken at each. Of this number, 189, 61 proved to be one or more parathyroids. In other words, about one-third of the pieces that were supposed to be, from their anatomical appearances, relations, positions, etc. to be parathyroids were parathyroids. It was interesting to note what the other two-thirds were. There were 82 pieces of thyroid tissue; this included little globular masses on the surface of the thyroid; also a number of accessory thyroids, small lobules of thyroid tissue not attached to the organ but independent and of wide distribution. There were 36 lymphatic glands which were not to be distinguished from parathyroids. There were 10 remnants of thymus in adult men; they were surrounded by vascular connective tissue. Three masses contained nothing but fat. Three showed nothing but dense connective tissue containing a number of blood vessels. There was one mucous gland, the nature of which could not be definitely determined; it lay in contact with the larynx, with its lateral wall, and it was afterwards thought that it might possibly be a salivary gland, although it did not correspond to the histological structure of the salivary glands. Out of 189 pieces there were 61 parathyroids, 82 thyroids, 36 lymphatic glands, 10 thymus remnants, 3 fat, 3 connective tissue and 1 mucous—a total of 196. In addition to these adult autopsies, 28 pieces were taken from infants, and of these 11 were parathyroids, giving the same percentage as in the adult. Nine were thyroids. Six were thymus remnants. The difficulty in recognizing parathyroids was due to several things, such as: (1) The size of the organ. The textbooks state that they vary from 3 to 5 millimeters, but he said it should be remembered that these glands vary from a maximum size of 5 millimeters down to a microscopical size, in some not being more than 15 micromillimeters in diameter. (2) Position. Some are found where one least expected to find them. When first described by Cohen it was stated that the typical tissue consisted of four parathyroids, two on the inner and two on the outer side, but they had found that only once. (3) Shape. This was variable, but they were usually small ovoid bodies. He believed that it would take a very heroic surgeon to cut down upon the gland with any idea of removing all the parathyroids from one individual. He might find one or two, but often he would not know whether he had left one or two behind. Little was as yet known regarding the pathology of the parathyroids, but the most frequent condition found was an increase in the connective tissue; this might be interstitial, invading the entire parenchyma of the gland and passing into the individual cells. Or it might follow along the course of the blood vessels and result in a perivascular increase of tissue. The increase of connective tissue was often replaced by fat.

Dr. Rogers said he began to study parathyroids after a death from Grave's disease following operation; in this case he believed the removal of the parathyroids might have been the cause of death. In man as well as in animals he said it was impossible to say that one had removed all the parathyroids; only those who had tried realized how difficult it was to get these out. In some animals, as the dog, they were about the size of the head of a pin. In every operation upon dogs the removal of the parathyroids resulted in convulsive seizures. He said he had seen a pup with parathyroids removed go into convulsive attacks.

Dr. James J. Walsh said that two years ago he began to study the influence of parathyroids in Basedow's disease, and was quite discouraged with his results. The cases numbered four, two being quite mild. One woman practically claimed that she was cured. In two severe cases there was practically no effect, and at the end of three or four weeks after increasing doses, the symptoms were worse. MacCallum had given his opinion that there was no connection between parathyroids and Grave's disease. Dr. Walsh said there was a great deal of speculation regarding the parathyroids, but the results of actual investigation was expected to yield light upon the subject.

Dr. Charles L. Dana said he had used the parathyroids in one patient with a remarkable change in the tremors, and under the influence of but one bottle of the gland. The next bottle used produced no such effect. His results in this and other cases were not at all satisfactory, because he was not sure whether or not he was really using the gland.

**The Röntgen Ray as a Factor in Medicine.**—Dr Arthur Holding of Albany read this paper, calling attention to general facts encountered while doing special work in this line. Röntgen's discovery ten years ago was not only of diagnostic but also of therapeutic value, having certain physiological action, with indications and contraindications.

Operators suffered the most, and he knew of three who had departed this life as the result of *x*-ray injuries. In his own experience he had encountered thirty operators who had been troubled with chronic ulcerations, some requiring amputations of fingers and arms. The problem of using the *x*-ray with safety could only be solved by the operators themselves. Screens had been devised for protecting the operator, and various protectors had been suggested, some being worn by the operators, others being placed about the tube, etc. Metal of high specific gravity should be utilized, and yet should not be too cumbersome. A description of such a device here followed. He referred briefly to the use of radium in cavities, and places where the *x*-ray could not reach. Slides were shown demonstrating various kinds and grades of *x*-ray burns. He also presented rubber tissue in which bismuth was incorporated, which was to be worn by the operator, protecting large portions of the body.

Dr. Hermann Grad said that a consideration of the dangers in using the *x*-rays was very important, and no operator should use the rays without protecting himself from injury as much as was possible. The use of the Röntgen ray in medicine he believed had come to stay. Instances of its diagnostic value were numerous. It was important, too, that the medicolegal aspect be considered, and he cited an instance which illustrated the necessity of having *x*-ray pictures in court. The court had not recognized the necessity of *x*-ray diagnosis, but seems to be favoring it more and more. Difficulty, too, was encountered in the interpretation of the pictures; the trained eye even would make mistakes. One should be extremely careful to guard himself against *x*-ray burns, especially when the rays were being used for diagnostic purposes.

Dr. Lewis Gregory Cole believed that all should be very thankful for any form of protection against the action of the rays. During the past two years he had been experimenting with the rays, and, in an article published last spring, he proved three distinct varieties of rays to exist, one of which was direct and traveled in a straight line, was neither diverted nor deflected. Another variety was from the walls of the tube, passing in all directions from the surface of the glass, and these rays he believed to be just as dangerous as the direct rays. They formed from 30 to 75 per cent. of the energy of the tube. When they struck the body they caused secondary rays to be generated in the body. He believed the only safe plan was to have the tube in one room and the operator in another with sufficient protection between, *i.e.* thick brick walls, or lead-lined doors with peep-holes of glass. Dr. Cole said that last spring he began to lose all his finger nails, and then lost the hairs on his arm. During the summer he was not exposed to the influence of the rays, and he was exposed to fresh air and sunlight. When he left the city there was not a hair on his arm, while to-day there were two hairs where originally there was but one. He asked why this happened—was it the sunlight, or what?

Dr. Henry G. Piffard said that in 1895, when Röntgen announced his discovery, he verified the fact and photographed the unknown rays. He used a four-inch coil and experimented off and on. But prior to Röntgen's announcement of his discovery Dr. Piffard did not dream of the unknown forces he brought to notice. Dr. Piffard said that he knew that he was dealing with something with bad effects about which he knew nothing, and he experimented no further with these rays for several years. He waited for somebody else to find out about them. He thought it was too dangerous a thing for him to be experimenting with. After four or five years' use of the *x*-rays he learned that they could be relied upon with a reasonable expectation to cure in certain cases, but other and better ways should be adopted if possible. There seemed to be a fascination in *x*-ray work that was difficult to eliminate. They did not know exactly what came from the tube. Rays penetrated different distances, some simply burning the skin and sterilizing the sexual organs. Why did they burn the skin? Because the rays were absorbed by the skin. If they penetrated through the skin such an effect would not happen. Only when the rays were absorbed by the skin was the skin burned. Therefore, to prevent this burning something should be placed in front to absorb these rays. The Germans had found pieces of leather would do this; leather cut off the burning rays, but allowed the other and useful rays to penetrate. Dr. Piffard had gone even further in this line. Glass was absolutely protective, and he was now endeavoring to have made for him a glass for such protection.

Dr. Margaret A. Cleaves said that the rays should be handled with care; they certainly constituted an agent capable of harm, although she had never seen any untoward effects from their use. With regard to the question as to whether it was the fresh air or sunlight that caused a return of the hair in Dr. Cole's case, she unhesitatingly believed it to be the effect of the sunlight. She had never had a patient suffer an *x*-ray burn or any untoward effect upon the skin. The skin of her own hands had remained smooth and as perfect as it ever had been, because she was careful in the handling of this agent. She never gave the *x*-ray without exposing all to the arc light.

Dr. Arthur Holding, in closing, said that there was a great deal of trouble encountered in getting the kind of tube one wanted for diagnostic work. There were not a great many enthusiasts about the therapeutic value of the *x*-ray. A great difficulty was in obtaining proper pictures for diagnosis, particularly if the condition was situated in the deeper parts.

---

**Intestinal Antisepsis: Its Theory and Application.**—W. C. Abbot claims for intestinal asepsis the reduction of the number and potency of the pathogenic bacteria in the intestine by the use of appropriate remedies, not the rendering of the canal entirely aseptic, a thing that is manifestly impossible. The débris of ingested food becomes, in deranged conditions of health, a nidus for the growth of germs. In most acute diseases food is not assimilated, the body chemistry is deranged, and the intestine becomes full of fermenting material ready for the growth of germs. Poisons are absorbed along the course of the intestine, and produce their toxic effects. Constipation causes this fermenting mass to remain in the bowels, or a part is rejected, leaving plenty behind in the folds and pockets of the intestine. The first thing to be done to render the intestine less septic is to remove as much as possible of the contained material, by the use of moderate doses of calomel. This at the same time stimulates the intestine and the liver, and causes the peristaltic action of the bowel to be encouraged. A saline is then given, causing an excess of serum to be poured out, and the stomach and intestine are made clean for the action of the sulphocarbolates, which are inimical to all germs, while at the same time not harmful to the most delicate membranes. Those used are the sulphocarbolates of zinc, lime, and soda, separately, or in combination. Under their use hyperpyrexia lessens, tympanites and foul tongue pass away. Digestive and febrile diseases of all kinds should be treated in this way. The sulphocarbolate of zinc may be given one grain, repeated every half hour to two hours, gradually increasing to 5 grains at each dose. Even two drachms in 24 hours may be taken without harm. When they have had the desired effect the stools are no longer black from bismuth combined with the sulphocarbolate, but take on a gray and then a normal brown color. The zinc is more astringent and antiseptic, the soda more antacid, while chronic cases with cachexia find the lime salt act as a tonic nutrient. The sulphocarbolates are very soluble, and hence are most useful. Assimilation soon begins to improve, and the microscope fails to find bacteria in the stools. Absorption occurs, not of poisons, but of properly digested foods. Opiates and anodynes in such cases only lessen the pain and do not do away with the poisoning.—*Alkaloidal Clinic.*

## Books Received.

*While the* Medical Record *is pleased to receive all new publications which may be sent to it, and on acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 14, 1905:

| | Cases | Deaths |
|---|---|---|
| Measles | 81 | 5 |
| Diphtheria and Croup | 219 | 19 |
| Scarlet Fever | 69 | 4 |
| Smallpox | . . | . . |
| Chickenpox | 55 | . . |
| Tuberculosis | 302 | 141 |
| Typhoid Fever | 124 | 20 |
| Cerebrospinal Meningitis | 4 | 9 |
| Typhus Fever | . . | . . |
| Yellow Fever | . . | . . |
| Cholera | . . | . . |
| Totals | 854 | 198 |

**Bradycardia.**—G. A. Gibson says that the term bradycardia has been employed to denote reduction of the pulse rate below the limits of health. It is purely a symptom. The causes can be divided into extrinsic and intrinsic. The condition may be the result of personal peculiarity or family tendency. Here the nervous system is the dominant factor, and the bradycardia is not pronounced. Tumor and abscess of the brain, sinus thrombosis and meningitis, diseases and injuries of the upper spinal column, and pressure on the vagus may all be causes. Reflexes from various organs, connected with pain or stress; pleural or pneumonic diseases, inflammation of the ducts of the liver, or calculus; stomach disturbances, intestines, kidneys, and pelvic viscera may all affect the heart. Melancholia, hysteria, and hypochondria, faulty body chemistry, and even the influence of the will may produce it. Toxic agents—lead, digitalis, and microbic poisons affect it. Also sclerosis of arteries and cardiac degenerations. In nervous and toxic cases generally the whole heart acts slowly. It may depend on the loss of conduction of pulsation from auricles to ventricles—that is, lessened ventricular action. Such is the condition in arterial degeneration and myocarditis. There may be no other symptoms present, or there may be breathlessness and sensation of palpitation or tremor. Pallor is frequent; arterial tension varies; generally the heart is enlarged; the impulse varies as to strength, and the sounds may be clear, or murmurs may be present. There are also symptoms of whatever condition acts as the cause. Paroxysmal forms are usually accompanied by nervous diseases. The condition may be paroxysmal, or persistent, or, with a slow heart, there may be periods of still slower beat. When there are frequent jugular pulsations without radial pulse of an equal frequency, the auricles beat more often than the ventricles, or some of the ventricular pulsations are feeble and abortive. A heart block may be produced by a lesion of the ventricles, a disturbance of the vagus, or damage to the conducting fibers. In cases where there are nervous diseases present the symptom is due to sclerosis of cerebral vessels When there is stress of circulation the blood supply to the brain is insufficient. There is a condition of irritable weakness of the inhibitory mechanism; impulses are sent to the heart; it is inhibited, and we have an attack of bradycardia. The condition is always of serious import, but the outlook is not necessarily fatal. When there are toxic influences the treatment is eliminative; if microbic, supportive treatment is in order. Strychnine is an antidote to most of these poisons. When there is an arterial spasm the nitrites must be used. When there is cardiac degeneration the iodides are useful, with strophanthus or digitalis.—*Edinburgh Medical Journal.*

### OBSERVATIONS UPON THE CAUSE AND TREATMENT OF PERINEAL ABSCESS AND OF PERIURETHRAL SUPPURATIONS ABOVE THE TRIANGULAR LIGAMENT.*

By SAMUEL ALEXANDER, A.M., M.D.,

NEW YORK.

SURGEON TO BELLEVUE HOSPITAL, PROFESSOR OF DISEASES OF THE GENITOURINARY SYSTEM IN CORNELL UNIVERSITY MEDICAL COLLEGE.

The term "perineal abscess" has not an exact significance. It is used to describe any suppuration that involves the tissues of the perineum without regard to the extent, or cause. This term includes, therefore, the conditions described as periurethral abscess, urinary abscess, infiltration and extravasation of urine, suppurative cowperitis, periprostatic abscess. The clinical phenomena of these conditions are not the same, but the essential cause is the same in each, viz., microbic infection extending from the urethra, as the result of either disease or injury.

Perineal abscess may be associated with infiltration of urine; but infiltration of urine is not an essential causative factor. Perineal abscess may be associated with stricture of the urethra, but it occurs quite frequently when stricture is not present.

Perineal suppuration occurs either as a circumscribed abscess limited to the perineum, and often to one side of the perineum, or as a rapidly spreading diffuse phlegmon which extends outside the limits of the perineum into the scrotum, the penis, and the abdominal wall. A circumscribed abscess becomes diffuse, under conditions which provoke and favor the spread of infection in the tissues; this is often the result of urine leakage.

It is to the infections of the perineum which result in circumscribed abscess, that I wish to call attention in order to define their cause, and to describe a method of operative treatment which I have used for a number of years, which differs in principle and technique from that usually followed.

The opinion is held very generally that circumscribed abscess of the perineum is not in many cases of urethral origin. It is claimed that it can be efficiently treated by simple incision and drainage, without opening the urethra except in cases in which there are distinct signs of urinary infiltration. This view of perineal abscess and its treatment is erroneous; but because it is so generally accepted, it is necessary to discuss the questions which underlie it.

Cases of circumbscribed perineal suppuration may be divided into two groups, viz., 1. Those in which abscess occurs associated with pronounced urinary obstruction, caused by urethral stricture. 2. Those in which there is no urethral stricture. This is not simply a clinical distinction, but is in accord with the pathology of these infections. It will appear later, however, that the line between these two varieties cannot be too sharply drawn, and that there are many phenomena common to both.

Perineal abscess, when it is treated simply by incision and drainage without opening the urethra, is followed very often by a recurrence of the abscess at the original seat of the infection. Of this fact I became convinced many years ago. The cause of the recurrence I was led at first to believe was urinary infiltration; to prevent this I began to treat these cases by opening the urethra in the perineum, and draining the bladder for a few days, in addition to evacuating the pus from the abscess. In many of the cases treated, it was impossible to discover at the operation any communication between the urethra and the abscess, nor did the abscess in these cases contain any urine. In cases in which there was communication between the abscess and the urethra, the signs of infiltration of urine often were slight.

As in some of the cases in which the membranous urethra was opened, but in which there was no urinary infiltration, the abscess recurred, I began an anatomical investigation of all cases of perineal suppuration admitted into my service at Bellevue Hospital, in order to find out, if possible, the exact source of the infection, and the cause of the recurrence. I discovered that in a large number of cases of abscess of the perineum, in which the pus seemed to be altogether below the triangular ligament, and to be limited to the perineum, there were also foci of suppuration situated above the triangular ligament. These latter were found in the prostate, and alongside of the membranous urethra posteriorly. They seemed to have originated in the glands of the prostate, the glands of Littré, or the glands of Cowper.

These collections of pus did not always communicate with the perineal abscess, or at least there was apparently no communication. They were discovered only after the urethra had been opened and the posterior urethra explored by the finger. In other cases the suppuration in the perineum was unmistakably due to an extension of the infection from an abscess which began above the triangular ligament. In some of these cases the abscess had opened spontaneously into the urethra before the operation, and the pus was draining imperfectly into the canal. Unless the urethra had been opened, the presence of these abscesses would not have been suspected or discovered at the time of operation.

The recurrence of a perineal abscess in cases of urethral obstruction from stricture, might be explained by a recontraction of the stricture after operation, and subsequent urinary infiltration above the obstruction; but in a great number of cases in which the abscess recurred after an operation by simple incision, I could find no stricture, and no urinary infiltration, nor any direct anatomical communication between the abscess and the urethra. At that time it was not clear to me how pathogenic microorganisms could invade the perineum and produce suppuration, when the urethra was apparently unin-

*Read before the American Association of Genitourinary Surgeons at the annual meeting at Montreal, June 13, 1905.

jured; nor could I explain cases of rapidly spreading diffuse phlegmon, seemingly the result of urinary extravasation, in which no opening in the urethral wall was discoverable.

I was engaged in the study of these questions, when in 1892 Delbet published his observations upon the dilatability and distensibility of the urethra, and his theory of urinary infection of the tissues about the urethra.

By a series of carefully conducted experiments upon fresh post-mortem subjects, Delbet claimed that every urethra has a physiological capacity for distention. If this is exceeded, leakage of urine into the tissues occurs through minute fissures in the mucous membrane. A comparatively feeble pressure may effect this, and he found that the most common situation of these fissures was in the perineal urethra. He explained the occurrence of periurethral abscess and perineal abscess by a microbic infection and urine leakage through these very minute fissures in the urethral mucous membrane.

This theory might explain the cases in which the suppuration is below the triangular ligament; especially those cases of abscess which occur in the course of acute inflammations of the urethra treated by forced injections or irrigations, and those which occur from narrow urethral stricture. In the latter the fissures are caused by the pressure of the urine above the stricture where the urethra is dilated and thinned. It does not explain, however, the occurrence of perineal abscess when there is no urethral stricture, nor those cases of abscess occurring in acute gonorrhea, in which no local treatment has been used in the urethra.

In confirming the results of Delbet, I made a number of dissections of pathological specimens of perineal suppurations, and was convinced by these that in some cases at least the perineal suppuration was an extension of an infection from the urethral glands above the triangular ligament. It was not, however, until 1903 that the truth of this view was demonstrated fully by the investigations of Motz and Bartrina.

These observers undertook to investigate the cases of cowperitis preserved in the Museé Necker; and they were led to extend their study to all cases of perineal suppuration in which the preservation of the specimens made it possible to form a conclusion as to the origin of the infection.

These authors call attention to the situation of the glandular appendages of the urethra; and more especially to the great number of the glands of Littré in the membranous portion, and to the inconstant masses of glands resembling in structure the glands of Cowper situated in the bulb of the corpus spongiosum—"the glands of the bulb." They conclude that perineal abscess when not caused by mechanical tears or rupture of the urethra, is the result of an infection which begins in these glands, or in the glands of Cowper or in the prostate, and extends into the perineal tissues. But they state that in the specimens examined the infection was not confined to the glands in one situation, and that the primary source of the perineal abscess could not always be determined definitely. For example, a perineal abscess may begin almost simultaneously as either a cowperitis, a littritis, a bulbitis, or a prostatitis—and clinically it is impossible often to distinguish between a littritis and a cowperitis.*

* In eighteen specimens of stricture complicated by perineal suppuration examined, in which the source of infection could be definitely made out: In three specimens it was due to a cowperitis, a bulbitis, and a littritis; in two to cowperitis and bulbitis; in five to cowperitis and littritis; in one to cowperitis and periprostatis. In the eighteen specimens examined there were: Four with urinary abscess; six with simple perineal suppuration; eight with infiltration of urine; but in three of these eight cases there was no opening into the urethra. Of these eight cases: In five there was a cowperitis; in one a bulbitis; in one a littritis; in one a periprostatitis.

A perineal abscess may be associated with infiltration of urine or there may be no urine leakage. When the infection from the glands extends alongside of the urethra, the abscess may open spontaneously through the mucous membrane, and urine escape into its cavity. When this occurs a simple circumscribed perineal abscess, suddenly becomes diffuse. The escape of foul and infected urine, especially of urine which undergoes rapid ammoniacal fermentation, into a simple perineal abscess, increases the virulence of the infection, and causes the very grave symptoms which are observed in the course of diffuse perineal phlegmon.

But an acute diffuse perineal phlegmon may occur with all the signs of rapid urinary extravasation, suppuration, and rapidly spreading gangrene, without any opening into the urethra, and without urinary infiltration. In this type of cases the fluid found in the tissues is not urine, but a septic edema. The intensity and extent of the phlegmon does not depend upon urine leakage, but upon the presence of a specific pathogenic microorganism.

In certain cases of circumscribed abscess, the evolution of the infection is slow, and the urine infiltration is slight. In these the tissues of the perineum are gradually transformed into hard masses of inflammatory tissue, called "urinary tumors." These often open upon the surface of the skin of the perineum and scrotum, and fistulous tracts are formed from which urine escapes. This condition usually occurs in cases of narrow stricture which have been neglected.

The observations of Motz and Bartrina and those of Delbet, I have confirmed in many particulars. They correspond with my clinical experience, and are in accord with the general principles of the operative treatment which I have employed with increasing success for more than ten years, in all cases of perineal suppuration. I call attention to this operation, since I can recommend it now not only as justified by the clinical results obtained, but as being in accord with our present anatomical and pathological knowledge of perineal suppurations.

The view that perineal abscess in cases of narrow stricture is due to ulceration of the urethra above the point of stricture, cannot be accepted. It is only necessary to study these cases post-mortem to find that the ulcerations are usually very small and superficial, and confined to the mucous membrane; they rest upon an indurated base, the result of a protective inflammation, which is impervious to liquids. An ulceration sufficiently rapid in its evolution to permit the escape of urine from the urethra into the surrounding tissues is the result of periurethral suppuration or of mechanical injury.

The source of the infection in a perineal abscess I believe is always from the urethra. The infection may occur in three ways: (1) Through the glands connected with the bulbous or membranous portion, *i.e.* the glands of the bulb, the glands of Cowper, or Littré's glands, or the prostate; and from these extends into the perineal tissues; (2) it may occur through small fissures in the mucous membrane of the urethra (Delbet); (3) it may be the result of a more or less extensive mechanical rupture of the urethra from external or internal violence. Infiltration of urine occurs and plays a prominent part in the infection of some cases, but often it is absent. It is not an essential causative factor in all cases. Stricture of the urethra may or may not be present.

Delbet's views as to the ease with which the mucous membrane of the urethra may become fissured by slight overdistention, makes it evident that forced irrigations and injections favor periurethral infection. This has been my experience clinically. Irrigation of the entire urethra from the external meatus without using a catheter is, I believe, bad; both in principle and practice. The deep urethra should not be irrigated except through a catheter. Injections should never be used forcibly, and in quantity should not exceed the normal capacity of the urethra. There are some cases of perineal abscess which occur during the course of an urethral inflammation, in which the immediate exciting cause of the suppuration is not apparent. Abscess occurring in acute urethritis in which no local treatment has been used, is an example of these.

Periurethral suppuration beginning in the urethral glands may continue for a long time before the infection extends into the perineum; this is especially true in cases of narrow urethral stricture and in cases in which there has been repeated attacks of urethritis.

An early diagnosis of periurethral suppuration is of great importance. In all cases in which perineal infection may occur, the prostate, and the membranous urethra, should be examined by rectal touch, in order to detect the first signs of suppuration; and the perineum should be carefully examined by rectal and external touch combined.

When there is periurethral suppuration above the triangular ligament, originating either in Cowper's or Littré's glands, there is a fullness and often fluctuation found in front of the apex of the prostate, either on one or on both sides of the membranous urethra. There is also an edematous condition of the tissues of the anterior wall of the rectum. The edema sometimes extends up over the posterior surface of the prostate. When the prostate is the seat of an abscess, there is an increase in its size and changes in its outline which can be detected by rectal touch even in cases in which the abscess has opened spontaneously into the urethra, or in those in which fluctuation is absent.

When a perineal abscess originates in Littré's or Cowper's glands, and subsequently invades the perineum, the course which the pus takes is along the wall of the membranous urethra, and it invades the perineum close to the opening in the triangular ligament. The communication between the suppuration above the triangular ligament, and the perineal abscess, is usually by a sinus which is found above and on one side of the bulb and close to the opening through which the urethra passes.

When a littritis and a bulbitis occur simultaneously, the suppurating focus above the triangular ligament may open spontaneously into the urethra and not communicate with the perineal abscess; the latter being due to extension of infection from a bulbitis. Suppuration about the membranous portion of the urethra, arising from a littritis, or a cowperitis cannot be efficiently drained without opening the membranous portion of the urethra.

When suppuration begins above the triangular ligament, it may extend into the ischiorectal fossa, as well as into the perineum. This occurs in one or two ways: The pus burrows either beneath the posterior border of the triangular ligament, a little to one side of the middle line and passes directly into the ischiorectal space; or it invades the perineum first and later on passes the limits of the deep layer of the superficial fascia, as the result of necrosis of this membrane.

Ischiorectal abscess associated with perineal abscess occurs with or without urinary infiltration: its occurrence seems to be frequently associated with the latter. I have met, however, with rapidly spreading infections from Littré's glands and Cowper's glands, which destroyed the deep layer of the superficial fascia, and extended into the ischiorectal fossa, without finding any communication between the perineal abscess and the urethra. In one of these, Case VII, this layer of the perineal fascia was found perforated by irregular necrotic areas, the tissues were gangrenous, but there was no evidence of urinary infiltration.

Perineal abscess is often associated with suppurating foci in the prostate, and these are found only after opening the urethra. The abscess may have opened spontaneously before operation into the urethra. The exact relation between prostatic abscess and perineal abscess was for a long time difficult to explain; recent observation has convinced me that the latter is caused usually by the extension of infection from Littré's or Cowper's glands, or the glands of the bulb, coexisting with the prostatic suppuration.

It is only within the last three years that I have discovered that the cases of perineal abscess which formerly I thought were caused by prostatic or periprostatic suppuration, are due to infection extending from the urethral glands, which are involved coincidently with the prostatic abscess.

The symptoms and physical signs of perineal abscess can be gathered from the histories of the cases appended to this paper, and it is unnecessary to consider them at length. I wish, however, to call attention to the necessity of making a thorough examination for the beginning of periurethral suppuration, even before the infection has invaded the perineum. In cases of difficult and painful urination, when there is deep seated pain, or tenderness in the perineum; or when there is a perineal swelling, an examination by rectal and external palpation combined should be made to detect suppuration. It is not necessary to wait until an abscess is fully formed in the perineum, and fluctuation is present to decide the diagnosis. As soon as periurethral infection occurs, an operation is indicated, to prevent further extension, and to hasten the patient's recovery.

There are many at the present time who believe that infection of the urethral glands and of the prostate can be treated successfully without operation. It is a waste of time to employ rectal irrigation or massage or any of the numerous local measures so often employed in the treatment of these conditions. The cases which seem to get relief from these measures usually later on develop abscess; or, if they are relieved, it is by the spontaneous opening of the abscess into the urethra; the opening in many cases is insufficient to drain the abscess, and so these cases remain with an incurable urethral discharge, and in addition are exposed to the danger of recurrence of the abscess.

**The Operative Treatment of Perineal Abscess.**—This should be in accord with the anatomy and pathology of these suppurations. The treatment of these cases generally is defective, because the necessity of opening the membranous urethra and of draining the pus foci which exist above the triangular ligament is not understood or is disregarded.

It does not seem to be understood that perineal abscess is either directly the result of periurethral suppuration above the triangular ligament, or is in nearly all cases associated with suppuration in this situation as the result of coincident infection of the urethral or prostatic glands. It is necessary therefore to open and drain the perineal abscess, and also to open the membranous urethra, and to drain the

foci of suppuration above the triangular ligament.

A perineal abscess is opened by a free median incision extending from the scrotum to three-fourths of an inch in front of the anus. The deep layer of the superficial fascia is divided for the entire extent of the incision, and the pus of the abscess is evacuated. The abscess cavity is cleansed of all necrotic tissue, and any sinuses or pockets are opened. The membranous urethra is opened upon a staff with a wide median groove; this incision should divide the floor of the canal and the lower border of the triangular ligament, and should extend from the bulb of the urethra to the apex of the prostate. The forefinger of one hand is passed into the urethra through the perineal incision as the staff is withdrawn. A careful and systematic exploration is then made for any foci of suppuration; and it is sometimes useful to make counter-pressure with the finger of the other hand upon the anterior wall of the rectum, during the examination.

When there is suppuration in or about Cowper's glands or the glands of Littré, a soft, sometimes fluctuating, spot is felt at the side of and below the membranous urethra. If these pus foci have opened spontaneously into the urethra the opening or openings can be felt as round or oval holes on the side, and sometimes near the roof of the canal. If the mucous membrane of the membranous urethra is still intact over the abscess at the time of operation, it is to be gently torn through by the fingernail. If the abscess has opened spontaneously before operation, the openings in the urethra are united by tearing through the bands of diseased mucous membrane which separate them. The tip of the finger is passed into the abscess cavity, which can be explored. This should be made level with the floor of the membranous urethra by gently tearing with the fingernail the mucous membrane toward the perineal wound; the pus can then drain into the incision made in the urethral floor. Abscess in the prostate is similarly treated when present. The bladder and wound are washed out, and the former is drained by a large catheter, No. 28 to 30 F. The perineal abscess cavity should be drained with a few strips of iodoform gauze.

The drainage tube is retained for two, sometimes for three days, and after its removal the case is treated as any perineal section. A steel sound as large as the external meatus will admit without pain is passed at the end of one week and once a week afterwards until the perineal wound has closed. In cases of narrow stricture, the urethra at the time of operation, is rapidly dilated by tunneled sounds passed over a whalebone guide until it can admit an Otis urethrotome; then after opening the membranous urethra the stricture is cut by internal urethrotomy upon the roof of the urethra. In cases of diffuse perineal phlegmon, the same method of treatment is followed, but in addition, free incisions through infected areas of the skin and cellular tissues should be made wherever there are signs of "infiltration of urine."

In cases of traumatic rupture of the urethra from external violence, an early operation is imperative, even before there is any perineal infiltration; but I am opposed to the plan of attempting to unite by suture the divided ends of the urethra.

Objections which can be raised to the method of treatment just described on theoretical grounds, are answered by the results which have followed its use in my service at Bellevue Hospital. An abstract is appended of the histories of a few cases which have been taken from a very large number treated in this service, to illustrate the points which I have endeavored to make clear in this paper. The success of treatment depends upon the surgeon's knowledge of the anatomy of these conditions, which cannot be learned from a written description, but must be acquired by personal clinical experience and observation.

Case I. *Relapsing Perineal Abscess Due to Cowperitis; Slow Urinary Infiltration; Stricture; Operation; Recovery.*—H. G., age 26, U. S. Admitted November 12, 1901. Three years before admission he had a gonorrhea; he was treated by injections. An abscess formed in the perineum; this was opened in a hospital at Sheffield, England. The wound healed in three weeks. Two years later he contracted a second gonorrhea, which was treated by injections; in the seventh week of the disease a swelling appeared at the site of the old abscess in the perineum; this subsided without operation. Three weeks before his admission he contracted a gonorrhea for the third time. Two weeks later a swelling appeared in the perineum, which became very painful, and two days before admission to the hospital it broke through the skin and discharged pus.

He had noticed that for some time his stream was diminished in size, and he had some frequency in urination. There was present a swelling in the perineum on the left side of the urethra, which was quite hard, but there was deep fluctuation; leading into this swelling was a sinus, which did not discharge urine.

Operation on November 13. An abscess was found beneath the deep layer of the superficial fascia on the left side. A sinus was found leading into the urethra at the bulbomembranous junction. The membranous urethra was opened and a cavity was found on its left side, due to pericowperitis; this was opened into the urethra and the bladder was drained. A stricture at the bulb was cut internally to No. 30F. He was discharged cured on February 22, 1902.

Case II. *Abscess of Perineum, Due to Cowperitis and Littritis; Two Previous Attacks, one of Which Resolved; in the Other the Abscess Opened Spontaneously in the Perineum; no Stricture; no Urinary Infiltration; Operation; Cure.*—E. R. age 31, U. S. Admitted December 12, 1901. He had gonorrhea thirteen years before admission and again ten years later; the latter was rebellious to treatment, and at the end of the fifth month a swelling appeared in the perineum, which was painful; this subsided after a few days without operation. A year later he still had a urethral discharge, and a swelling reappeared in the perineum; this became hot and painful, and finally ruptured externally, discharging a large amount of pus, and he thinks that for a week some urine passed through the wound, but the sinus healed spontaneously.

One week before admission he contracted gonorrhea; the urethral discharge was profuse, and three days before admission a swelling appeared in the perineum. In the perineum there was a swelling about the size of a pigeon's egg, beneath the deep layer of the superficial fascia. Rectal examination showed the prostate normal in size; there was fluctuation about the membranous urethra and in the perineum. He had pain on urination; no obstruction to urination; no increased frequency.

Operation December 13. Perineal section: An abscess was found beneath the deep layer of the superficial fascia, in the lower portion of the abscess cavity; close to the bulb a sinus was found leading up to situation of Cowper's glands. The membranous urethra was opened and the abscess drained. No communication could be found between the urethra and the perineal abscess. The patient remained in the hospital for some weeks after his

recovery, and was discharged February 22, 1901, cured.

Case III. *Perineal and Ischiorectal Abscess Originating in Either Cowper's or Littré's Glands; Urethral Stricture; no Infiltration of Urine; Operation; Cure.*—D. McK., age 31, U. S. Admitted April 9, 1902. He had had four attacks of urethritis. One and one-half years before admission he noticed that his stream was becoming smaller; three months later he had retention of urine and was operated upon for stricture at Hudson Street Hospital, New York, by perineal section. Sounds were passed twice a week for two months after the operation. Ten days before admission he developed a urethritis; a week later a left epididymitis. He passed urine four times a day, twice at night; he had no chill and no retention. The day before admission he noticed swelling in the perineum, with pain on walking and pain on defecation. The swelling was confined beneath the deep layer of the superficial fascia. Rectal examination showed the prostate of normal size; there was marked edema of the anterior rectal wall; on the left side of the membranous urethra there was a swelling which extended out to the left. There was fullness and sense of fluctuation in the perineum on the left side, which extended down into the left ischiorectal fossa.

Operation on April 10; Median perineal section; about one-half ounce of pus was evacuated from beneath the deep layer of the superficial fascia. The membranous urethra was opened; no communication was found between the perineal abscess and the urethra, but an abscess was found on the left side of the membranous urethra and another in the ischiorectal fossa; these were drained, and the patient was discharged, cured on April 20.

Case IV. *Acute Perineal Abscess from External Violence; Retention of Urine; Urinary Infiltration Without Apparent Opening into Urethra; Operation; Cure.*—A. W., 37, Swede. Admitted the night of October 18, 1904. He had gonorrhea seventeen years before; nine days before admission he fell astride an iron rail, striking upon his perineum. He had severe pain in perineum at the time, and the next urine which he passed was bloody. During the following night he had to urinate every two hours, and passed blood at each urination. Pain in the perineum increased; his desire to urinate became more frequent. He noticed swelling in the perineum, and on the day of admission to the hospital he had retention of urine.

Examination showed a swelling of the perineum, extending up into the scrotum; the skin was red and edematous. A soft rubber catheter was passed and the retention was relieved. The operation was delayed until the following morning, October 19. External urethrotomy. An abscess was found beneath the deep layer of the superficial fascia; it was more on the right side than on the left side of the urethra. A communication between the abscess cavity and the urethra could not be found. The membranous urethra was opened. The bladder was drained. The patient made a good recovery and was practically well a month later, but had a small fistula, which persisted for nearly two months and then healed.

Case V. *Perineal Abscess; Bulbitis; Urinary Infiltration; Urethral Stricture; Operation; Cure.*—T. B., age 23, U. S. Admitted November 16, 1904. He had a gonorrhea fourteen years before; and symptoms of stricture with difficult urination for the past nine years, for which he had been treated by dilation with sounds. On November 10 he noticed pain in the perineum; this increased from day to day and was most severe during urination; he had no pain on defecation. On November 14 he noticed for the first time, a swelling in the perineum. The pain became so severe that he came to hospital for relief.

On admission he had almost complete retention of urine. There was a marked swelling beneath the deep layer of the superficial fascia with edema of the scrotum. A narrow stricture of the urethra admitting a filiform guide was found just in front of bulb.

Operation on November 17. Perineal section: Stricture was cut internally to No. 30 F. after first being rapidly dilated to No. 20 F. The perineal abscess communicated with urethra at bulb by rather large opening; source of infection probably in accessory glands of the bulb. Discharged, cured, December 17, 1904.

Case VI. *Case of Perineal Abscess, Due to Cowperitis Associated with Prostatic Abscess; no Urinary Infiltration; Operation; Cure.*—W. J. M., age 28; U. S. Admitted April 5, 1905. He had a gonorrhea when twenty years of age, and again two years later. He was treated by irrigations almost continuously for a year and sounds were passed at intervals. Four days before his admission he began to have pain in perineum, increased by walking and by sitting down. He had no pain or difficulty at urination. On the next day he noticed a swelling in the perineum.

On admission he had a swelling in the perineum more marked on the left side, but which extended somewhat beyond the median line. This was tender; the skin over it was red; it was about one and one-half inches long by three-fourths inches wide.

Operation April 5. Perineal section. The patient's urethra easily admitted No. 30 F. sound. There was no stricture. Beneath the deep layer of the superficial fascia an abscess was opened containing about two ounces of pus. The membranous urethra was opened, and on passing the finger into the urethra an abscess cavity was found on the left side, extending below and alongside of the membranous urethra. Another abscess was found in the left lobe of the prostate; this had opened into the prostatic urethra. These abscesses were drained into the urethra. The bladder was drained for twenty-four hours. The patient was discharged at his own request, on the tenth day, passing all urine through the urethra, and at the end of the third week was entirely well.

Case VII. *Perineal and Ischiorectal Abscess; Cowperitis and Littritis; no Infiltration of Urine; Operation; Cure.*—F. S., age 27. Admitted May 14, 1905. He had a gonorrhea twice, the first attack eight years before, and the second three months before admission. He was treated for the latter by injections for about five weeks. Three weeks before admission he began to have pain, and a swelling appeared in the perineum. He had no frequency or pain on urination and no difficulty in passing water. He had a moderate discharge from the urethra; the urine contained free pus and shreds. Examination showed a swelling on the left side of the perineum; this extended a little to the right of middle line. There was swelling over the ischiorectal fossa. Rectal examination showed tenderness and fluctuation about the membranous urethra.

Operation on May 15; Perineal section. On cutting through the skin down to the deep layer of the superficial fascia, this was found to be necrotic; there was a large abscess cavity on the left side of the urethra, which had burrowed also into the ischiorectal fossa. There was no communication between the perineal abscess and the urethra. After

opening the membranous urethra an abscess was found on left side which apparently began in Cowper's gland. The perineal abscess was cleaned, disinfected, and a counter-opening made to drain the ischiorectal fossa. On June 10 all urine was passed through the urethra.

Case VIII. *Perineal Abscess Caused by Double Cowperitis and Prostatic Abscess; Probably Tuberculous; Operation.*—E. Q., age 28. Admitted May 14, 1905. He denied all previous venereal disease. Three weeks before admission he contracted a gonorrhea. He was treated with injections by a physician and from the first had pain in the perineum and along the urethra; he had frequency of urination, but had never passed blood; he had pain on defecation. Six days before admission he noticed a swelling in the perineum; this was painful and was growing progressively larger. He had no difficulty in passing water. He had a profuse discharge from the urethra.

Examination showed a swelling in the perineum situated beneath the deep layer of the superficial fascia with fluctuation. Rectal examination showed the prostate enlarged on the left side; tender; the membranous urethra and the tissues surrounding it were soft and edematous. The urethra was not strictured.

Operation on May 15. Perineal section. On cutting through the deep layer of the superficial fascia an abscess cavity was opened; on exploring the deep urethra a large cavity was found on the side of the membranous urethra; this communicated with the abscess in the perineum; there was also an abscess in the prostate. The suppuration seemed to have begun in Cowper's glands and this was associated with prostatic abscess. A tube was introduced and the bladder drained for forty-eight hours. The perineum healed without complications. All urine was passed through the urethra after May 26th.

Case IX. *Mechanical Rupture of Urethra; Slow Infiltration of Urine; Circumscribed Perineal Abscess; Traumatic Stricture; Operation; Cure.*—J. E., age 26. Admitted May 15, 1905. He had gonorrhea seven years before admission and a second attack three years later complicated by an epididymitis. Three months before admission he fell from a height of thirty feet, striking on the perineum and inner side of thigh. He had difficulty in passing urine, and passed bloody urine. He did not have complete retention of urine, but noticed that his stream was for some time becoming progressively smaller. One month before admission he noticed a painful swelling on the right side of the perineum; the pain was increased by walking and by sitting down and by defecation.

Examination showed a deep-seated swelling on the right side of the perineum; this was painful upon pressure. It was hard, and there was no sense of fluctuation. There was no enlargement of the prostate. A narrow stricture, admitting only a filiform whalebone guide was found at the bulb of the urethra.

Operation on May 16. Perineal section. The stricture was cut internally to No. 30 F. with an Otis urethrotome, after rapidly dilating the urethra to No. 18 F. A small circumscribed abscess was found just above the bulb on the right side; this was opened; no communication could be found with the urethra; the infection seemed to have extended from the glands of the bulb. The bladder was drained by perineal tube. The tube was retained for forty-eight hours. The patient passed all urine through the urethra on May 27. Discharged May 31, and was entirely well on June 5.

## THE INDICATIONS FOR OPERATING IN ACUTE MASTOIDITIS.*

By PHILIP D. KERRISON, M.D.,

NEW YORK.

In determining the relation of surgery to disease, one should deduce one's facts from the cases which have recovered without operation as well as from those operated upon. Particularly does this seem to be true with regard to the indications for operating in acute mastoiditis. Competent surgeons, usually at one theoretically, often differ materially in practice. Whoever, therefore, feels called upon to dissent, even in the smallest particular, from the popular conception of what should constitute an indication for opening the mastoid, should have the courage to state his views, and give his reasons therefor. It is the relative surgical value of what are commonly considered the two cardinal physical signs of acute mastoiditis, that the writer wishes to discuss.

To review briefly the symptoms of acute mastoiditis, they may be stated somewhat as follows: The patient, during the course of, or convalescence from, an attack of acute purulent otitis media, may suddenly experience deep-seated pain in the region of the mastoid process. The aural discharge, which has perhaps been gradually decreasing in quantity, may follow one of several courses in order to show that recovery has been interrupted; *e.g.* it may (*a*) suddenly cease, this abrupt cessation being accompanied by no amelioration of the patient's condition, and being followed within a few hours or a few days by a still more copious flow of pus; or (*b*) the discharge may gradually increase in volume until it becomes necessary upon purely physical grounds to assume the involvement of accessory sinuses in order to explain the quantity of pus excreted during the twenty-four hours; or (*c*) the long continuance of the discharge may of itself be sufficient to warrant the inference of a necrotic focus more deeply seated than within the small tympanic cavity. With the appearance of mastoid pain, sleep is disturbed, insomnia becoming a more or less prominent symptom; and the temperature, which has run a normal course, or has returned to normal, may become elevated. As corroborating the above symptoms, the following two physical signs have come to be regarded as pathognomonic, viz., (1) Tenderness on pressure over the mastoid; and (2) bulging of that portion of the posterosuperior canal wall which immediately adjoins the drum-membrane.

The symptoms to be looked for, then, are *mastoid pain*, with consequent insomnia; *elevation of the temperature; certain quantitative changes in the character of the discharge; mastoid tenderness*, and *bulging of the posterosuperior canal wall.* The above rather meager clinical picture may be said to comprise practically all the symptoms that are characteristic of an uncomplicated case of acute mastoiditis.

Unfortunately, many cases of acute mastoiditis run their course with complete absence of one or more of the above symptoms. That extension necrosis of the mastoid cells may occur with absolutely no elevation of temperature, is a fact now fortunately recognized. Mastoid pain may also be absent or at least not sufficiently marked to be complained of by the patient. Where fever is absent, and pain inconsiderable, the subjective and constitutional phenomena are naturally not very characteristic. Fortunately, there is one physical sign which is never

*Read in Boston, on June 6, 1905, before the American Laryngological, Rhinological, and Otological Society.

wholly absent. Sensitiveness to pressure is probably at the onset always present over some point on the mastoid cortex.

In discussing the surgical value of the two physical signs above mentioned, it will be necessary to refer very briefly to certain points in the anatomy of the bone which bear more or less directly upon the pathology of the disease.

*Pain on Pressure over the Mastoid Antrum.*—If we were taught to regard the antrum, not as one of the mastoid cells, but simply as the posterior end of the tympanic vault, our conception of its true surgical significance would be more exact. In the fetus at term, the mastoid process, as such, does not exist, it being represented by a thin cartilaginous plate; yet the antrum is already an easily demonstrable cavity. In the seventh month of fetal life, also, the antrum can be demonstrated to exist, and at this period of its development, its walls are formed chiefly by the squamous portion of the future bone. While these facts are now fairly generally recognized by students of tympanic anatomy, their surgical significance is still somewhat obscured by statements in some of the older textbooks, which refer to the antrum as one of the mastoid cells, and describe the aditus ad antrum as a narrow passage by which it communicates with the tympanic vault.

The aditus is not a narrow passage connecting two bony cavities. It is distinctly a constricted portion of one and the same cavity. Careful examination of a large number of bone sections shows the aditus to consist of a comparitively large triangular space, the vertical diameter of which—*i.e.* measured from the center of its base above, to its inferior angle below—will average not less than 4 to 5 mm. Considered as one osseous space, the antrotympanic cavity may be described as one having a central constriction, and so bent upon itself that while its roof lies throughout in the same horizontal plane, its floor is lower anteriorly and posteriorly than at the center where encroached upon by the lower margin of the aditus.

The antrum, then, should not be thought of as a distinct bony cavity; nor is it an accessory sinus in the sense that the frontal, ethmoidal, sphenoidal, and maxillary cavities are accessory nasal sinuses. For, whereas hypersecretion may occur, and frequently does occur, within the nose without flooding these accessory cavities, it is difficult to conceive of any considerable accumulation of fluid within the tympanic vault which will not flow backward into the antrum.

This rather tedious statement of facts prepares the way for the following propositions, viz., (1) That acute purulent otitis media is probably always attended by an escape of pus into the antrum; and (2) the presence of pus within the antrum is not necessarily an indication of mastoid inflammation.

These conclusions seem fairly deducible from the mechanical relations of the various parts of the antrotympanic cavity; and from certain clinical facts now generally recognized. In the living subject the vault is more or less completely separated from the lower portion of the tympanic cavity by the following structures, viz., the neck and processus foliamus of the malleus; the lower angle of the body of the incus; the anterior, posterior, and external ligaments of the malleus, and the folds of mucous membrane covering them. With these structures *in situ*, it would seem more reasonable to assume the mechanical separation of the atrium and vault, than to recognize the vault and antrum as two distinct cavities. Pus in the vault, therefore, must, under pressure, pass in the direction of least resistance to the antrum.

Now, experience has shown that, in the majority of cases of severe tympanic infection, the suppurative process originates within the vault, rather than the atrium; in which case it seems obvious that pus accumulating within the vault must quickly invade the antrum. The fact, therefore, that many cases of severe suppurative otitis media recover without having produced any symptoms of mastoid involvement, would seem sufficient evidence that pus within the antrum may be reabsorbed without having produced any of the bone changes characteristic of a true mastoiditis.

To epitomize: *Acute purulent otitis media is commonly accompanied by the passage of pus to the antrum; and its presence there on opening the antrum is not necessarily an evidence of mastoid inflammation.*

Admitting the above as a working hypothesis, it is not surprising that marked sensitiveness to pressure over the antrum is present in many cases of acute purulent otitis media. With an acute inflammatory process involving the mucous membrane not only of the attic, but also of the aditus and antrum, and with the whole antrotympanic cavity subjected to the pressure of an accumulation of pus for which there is no adequate orifice of escape, absence of pressure tenderness over the antrum would mean a difference between this and all other regions of the body under like conditions. In other words, antrum tenderness may in such cases denote simply the presence of confined pus. Viewed in this way, this important danger signal is as much a logical outcome of the tympanic lesion as is its rapid subsidence a result of free incision of Shrapnel's membrane and other rational measures for the relief of an acute purulent otitis media.

Where antrum tenderness persists in spite of such abortion measures, its significance must of necessity be regarded as more grave.

*Pressure Tenderness Over the Mastoid Cells Proper.*—In the foregoing remarks, the writer refers only to that stage of the disease in which the inflammatory process is confined within the limits of the antrotympanic cavity. When the pus has found the way into the mastoid cells proper, the disease is by no means so likely to yield to the simpler surgical and therapeutic measures. The lining membrane of the cells in the lower portion of the mastoid process seems to possess but little power of resistance to the action of infective organisms, and the intercellular bone substance is exceedingly prone to undergo necrosis. The significance of mastoid tenderness must, therefore, vary somewhat with its location upon the mastoid cortex, its gravity becoming relatively greater as it extends downward below the level of the floor of the antrum.

*Sagging of the Posterior Canal Wall.*—A question which it may be permissible to reopen, is the surgical significance of sagging, or, better stated, of bulging downward and forward of the posterosuperior canal wall. Are we to continue to regard this as one of the cardinal signs of mastoid inflammation? Is the periostitis upon which this bulging depends, due to an extension of mastoid inflammation through that portion of the thick anterior wall of the mastoid process which enters into the formation of the posterior canal wall? Or is it rather an extension of inflammation by continuity of structure along the soft parts of the posterior canal wall from the tympanic vault? The writer believes that in the vast majority of cases this bulging of the posterosuperior canal wall is due to an extension of inflammation from the vault, and is not an indication of mastoid inflammation, which may or may not be present. This belief is based upon the following anatomical, surgical, and clinical facts:

1. *Anatomical.*—(*a*) A section of the temporal bone, more or less horizontal in direction, and passing through the posterosuperior canal wall, shows this to consist of a dense, and often thick plate of bone which should act as a natural barrier to the rapid extension of an inflammatory process from the mastoid cells to the membranous lining of the bony canal. (*b*) The intimate structural relation to Shrapnel's membrane to the membranous lining of the posterior canal wall provides a natural pathway for the extension of inflammation by continuity of structure.

2. *Surgical.*—While complete removal of all diseased bone is the first aim of mastoid surgery, this indication never in acute mastoiditis requires the removal of any portion of the bony plate which separates the mastoid cells from the membranous canal. In other words, the posterior bony wall is rarely, if ever, diseased. Why, then, if this bony partition is not involved in acute mastoiditis, should swelling of the membranous lining of the posterior canal wall be regarded as an evidence of mastoid inflammation?

3. *Clinical.*—(*a*) In cases of *chronic suppurative otitis media* in which extensive destruction of the membrana tympani has occurred, characteristic bulging of the posterior canal wall is never present; yet in such cases the posterior wall of the bony canal, as well as the mastoid cells, is often diseased. How is the absence of this physical sign to be explained except by the loss of continuity between the structures of the vault and those of the membranous canal?*

(*b*) There have been many cases of *acute purulent otitis media*, which, in spite of marked bulging of the posterosuperior canal wall, have recovered completely and permanently without operation and without having produced any marked signs of mastoid inflammation. Such cases have been repeatedly observed by others as well as by the writer.

Two facts, then, should be borne in mind, viz., (1) that this "sagging of the posterosuperior canal wall," whatever the exciting cause, is the result of inflammatory changes in its periosteal lining; *i.e.* is dependent upon a true periostitis; and (2) that in no structure of the body is swelling due to acute inflammation more likely to be prolonged than in the periostea. This is a recognized surgical fact. If, therefore, a somewhat protracted inflammatory thickening of the posterosuperior canal wall be regarded as an evidence *per se* of an acute mastoiditis, many cases may be operated upon in which mastoid inflammation has either never existed, or, having been present, has undergone resolution.

The writer wishes to emphasize the fact that not every case of acute purulent otitis media which develops antrum tenderness and bulging of the posterior canal wall is necessarily one of true mastoiditis; and that between the milder grades of tympanic infection and inflammation of the mastoid cells proper there is an intermediate condition—an empyema of the antrotympanic cavity—which yields quite happily to free incision of the drum-membrane and appropriate after measures. Antrum tenderness may mean, therefore, either a collection of pus in the antrotympanic cavity, or the early stages of a suppurative process within the mastoid cells. Which of these two conditions exists can be determined only by the manner in which the symptoms respond to treatment; *i.e.* their persistence or rapid disappearance after free incision of the drum-membrane and inflamed posterior wall. It is to be noted, however, that even in those cases which go on to rapid and complete recovery, the "sagging of the posterior canal wall" is one of the last symptoms to disappear.

*The indications for operating in acute mastoiditis* may be summed up somewhat as follows:

(1) Sudden cessation of the aural discharge, other symptoms persisting; deep-seated pain in the mastoid region; marked sensitiveness to pressure upon the mastoid *over an area extending well beyond the limits of the antrum.* These symptoms in the presence of a sudden or considerable rise in temperature would justify an immediate operation.

(2) In the absence of fever, the above symptoms, unless yielding promptly, *i.e.* in twenty-four to forty-eight hours, to abortive measures, would constitute a sufficient reason for operating upon the mastoid.

(3) Marked tenderness over the antrum, persisting four to five days after free incision of Shrapnel's membrane, would point to necrotic changes within the antrum calling for operative intervention.

(4) Marked variations in the quantity of pus discharged; its maximum flow being, apparently, too great to be explained by the tympanic lesion; its periods of diminution being coincident with the development of mastoid pain or tenderness (or both). Such a combination of symptoms constitutes one of the most positive indications for opening the mastoid.

(5) Mastoid tenderness having been present and having disappeared, a discharge from the tympanic vault, which resists all rational non-operative measures, may, by reason of its persistence, justify the hypothesis of a necrotic area in the aditus or antrum. In such cases an operation is often the only means of saving the integrity of the organ, and preventing serious impairment of function.

(6) Finally, evidences of mastoid involvement having been present, the development at any time during convalescence of symptoms of septic absorption—*e.g.* septic temperature, constitutional exhaustion, etc.—would, in the absence of other concurrent disease, constitute a positive indication for immediate operation.

It will be seen from the above that the writer recognizes a number of conditions as calling more or less imperatively for operative intervention. He is convinced, however, that a careful observance of the rule implied in the third clause will reduce very materially the number of cases requiring operation. That is to say, where tenderness is confined to the antrum and free drainage through the drum-membrane has been established, a delay of four to five days will, in many cases, demonstrate clearly the absence of mastoid disease.

Among the "indications for operating" the writer has not included bulging of the posterosuperior canal wall, because he believes this to be a physical sign of acute suppurative otitis media. It is of undoubted surgical value in pointing to a type, or perhaps stage, of tympanic infection, which must receive prompt and vigorous treatment in order to prevent an extension of the disease to the mastoid cells. Its persistence, however, after mastoid tenderness and other signs of mastoid involvement have disappeared, is no indication of mastoid disease, and should not be regarded as an indication for operative intervention.

The writer has purposely avoided any allusion to the bacterial character of the discharge, as influencing prognosis and treatment. Cases of streptococcus infection often yield quite readily to minor surgical measures, whereas others, in which only the milder pus germs are found, often prove most severe clinically. Until we can explain, therefore, the varying

* In cases of chronic suppuration otitis media in which the upper half of the drum membrane remains intact, exacerbations of acute inflammation not infrequently give rise to characteristic bulging of the posterior wall.

degrees of virulence exhibited in different cases by apparently the same germ, it would seem safer that the question of operation should be decided in each case chiefly by reference to the symptoms and physical signs.

In conclusion, the writer would like to cite two cases from his own practice:

Case I.—A. D., a girl eight years of age, was referred to the writer on January 15, 1904, by Dr. Howard Gillespie Myers.

*Previous History.*—Measles two years ago; no aural sequelæ. Has been subject during the past two years to somewhat frequent attacks of acute tonsilitis. Breathes normally.

*Present Attack.*—On January 5 developed acute tonsilitis. On the following day complained of pain in left ear, which persisted more or less constantly until January 10, when relieved by spontaneous rupture of drum-membrane. Five days later, symptoms recurring, I was called in.

At this time the child complained of earache. Temperature 10.6°. The whole drum-membrane is red, with pronounced bulging of Shrapnel's membrane; the bulging here is continuous, with marked swelling of the soft parts of the posterosuperior wall of the bony canal. Small perforation in posteroinferior quadrant of drum-membrane. Marked tenderness over mastoid antrum.

*Treatment.*—Under nitrous oxide anesthesia, the drum-membrane was freely incised—the incision being carried through the posterior segment of the tense membrane, through Shrapnel's membrane into the vault, and thence outward through the inflamed posterior wall. Leiter's coil applied to mastoid. Irrigation of canal with bichloride of mercury, 1 in 5,000 solution, every three hours. Leiter's coil removed at the end of twenty-four hours, and not replaced, in spite of the fact that antrum tenderness was still present. From this time the tenderness over the antrum became daily less marked, and had entirely disappeared on January 19, the fourth day after the myringotomy. Other symptoms were more persistent. The discharge showed but little tendency to diminution. On January 23, the incision in the drum-membrane having partially closed, and drainage being obviously insufficient, the original incision was repeated. Shortly after this, in spite of a rather free discharge, it was thought wise to discontinue irrigation and substitute the use of dry wicks of sterile gauze carried into the canal and against the opening in the drum-membrane, both of which had been previously cleansed and dried. The wicks were changed at first twice, and then once, daily. From this time the symptoms showed gradual, but satisfactory, improvement. The persistent sagging of the posterosuperior canal wall, however, was a cause of doubt and anxiety to the writer. Even after the opening in the drum-membrane was closed, and the tense membrane had regained a fairly normal appearance, the swelling of the posterior wall was marked. All other symptoms having disappeared, the writer felt justified in discharging the patient on February 11, the parents being instructed to report promptly any symptoms of relapse.

Three weeks later the patient was brought to the office for examination. There had been no recurrence of aural symptoms. The tense membrane was normal in appearance. Function, tested by acumeter and whisper, seemed perfect. The posterosuperior wall, however, still showed some thickening. The writer has heard, indirectly, that there has been no return of symptoms referable to the ear.

Case II.—Mrs. D. was referred to the writer on February 17, 1904, by Dr. S. A. Brown.

Previous history negative.

One week ago, as a sequela of acute rhinitis, patient experienced severe pain in right ear, which was relieved in a few hours by spontaneous rupture of drum-membrane. The patient is referred to me on account of continued discharge and return of pain. Temperature 102°.

*Examination of Right Ear.*—Small perforation in posteroinferior quadrant of drum-membrane. Shrapnel's membrane bulging, there being no line of demarkation between this and the swollen posterosuperior canal wall. Marked tenderness on pressure over antrum.

*Treatment.*—Under nitrous oxide anesthesia the posterior segment of the drum-membrane and the inflamed posterior wall were freely incised. The usual measures, *i.e.* rest in bed, catharsis, irrigation of canal q.3.h., with bichloride of mercury, 1 in 5,000 solution, were ordered. Patient advised that mastoid operation might be necessary. She was seen daily. Discharge, at first free, diminishing daily. On February 22 antrum tenderness was barely appreciable on firm pressure. One week later the incision in the drum-membrane had completely healed. The swelling of the posterior canal wall, however, had not subsided, and was again a cause of anxiety to the writer, who still shared the popular belief as to its grave surgical significance. This anxiety the patient did not share. She was free from pain, and to all intents in her general health, and but for a slight impairment of hearing would probably have regarded her cure as complete. The correctness of this view was demonstrated by the complete subsidence of all symptoms, the inflammatory changes in the posterior canal wall being among the last to disappear.

These histories might be reinforced by others in which the disease ran a similar course. They suffice, however, to illustrate clinical phenomena, which the writer has observed in a large number of cases. They were selected chiefly because, having occurred considerably over a year ago, sufficient time has elapsed to justify the conclusion that recovery was complete.

58 West Fifty-sixth Street.

## CONVALESCENTS; THEIR CARE FROM THE MEDICAL STANDPOINT.*

By LEE K. FRANKEL,
NEW YORK.
MANAGER UNITED HEBREW CHARITIES OF THE CITY OF NEW YORK.

Probably no more significant or valuable statement on the treatment of the tuberculous sick has been made in recent years, than the one uttered by Dr. John H. Pryor at the second meeting of the New York State Conference of Charities and Corrections held in New York in November, 1901. At this meeting Dr. Pryor laid down the dictum that it was the best public policy to take care of the consumptive at the right time, at the right place, and in the right way until he was well, and not at the wrong time, at the wrong place, and in the wrong way until he was dead. The thesis thus expounded has since that time become the basis of enlightened treatment of those who are afflicted with the "white plague," in all parts of the United States. It is not to our discredit to remark that in this sane procedure we have followed the practice of intelligent government in the old world; it is to our credit that we have early recognized the validity and sanity of the belief thus crystallized in Dr. Pryor's statement, and have also acted upon it with wisdom and intelligence. To-day in all parts of the United States we have special

*Read at the National Conference of Charities and Corrections, held in Portland, Ore., July, 1905.

hospitals and sanatoria for the treatment of tuberculosis, not only of the pulmonary type, but of the manifold forms in which this disease manifests itself. Only within the past year we have added to the list of these special institutions the Camp for tuberculous children, founded by the Association for the Improvement of the Condition of the Poor, at their sanatorium at Sea Breeze, N. Y. The splendid results that have been obtained indicate that the experiment was warranted and that similar enterprises will be established in other sections of the country in the near future.

It is probably due to the prevalence of tuberculosis and the ravages which it has made through the centuries, that it has gained such prominence and that as a result of the investigations of the best medical minds, we seem to be on the threshold of the day when the death rate from tuberculosis will be on a par with other diseases.

Generally speaking, it may be said that the cures which have been effected depend upon an early recognition of the disease, and the subsequent application of natural therapeutic measures, such as fresh air, good food, freedom from care and anxiety, and the subordination of the patient to the treatment, irrespective of time limits or the patient's economic condition. Both from the medical and the social standpoint it has been conceded as the essence of the subject that the victim of tuberculosis who desires to recover his health, must subject himself to a prescribed program, and regardless of any economic considerations, must undergo treatment, not until he begins to feel well, not until he again begins to feel strong enough to return to work, if he belongs to the working classes, but until the time, when, in the opinion of the medical practitioner, the last vestige of the disease producer, the tubercle bacilli, has been eradicated. It is true that even to-day this is not the case in many instances. Many patients return to their homes from sanatoria before they are discharged, and against the advice of the attending physicians. Others, under the impulse of economic necessity, sacrifice their restoration to health at the altar of their families, and become victims of paternal or filial duty, and of society's inability to make proper provisions for such contingencies. It is becoming more and more recognized by the medical as well as the social worker, that if we wish to effect a cure in a tuberculous patient the best medicine we can give him is to provide for his family in his absence. It is needless to say that we are dealing here only with the poor, and in particular with the respectable wage-earning element with whom sickness has exhausted the savings of years, and to whom the absence of the wage-earner for an indefinite period in a sanatorium spells ruin. This, however, is not the point which I wish to bring out at this junction. It is sufficient to demonstrate that in the treatment of the tuberculous patient it is universally recognized that the time factor is an important one, and that after the acute period of the disease has been passed, the upbuilding of the patient through proper food, pure air, freedom from worry, and through medical supervision is essential, and that this must be accomplished without regard to the length of time such treatment may require.

The same cannot be said of the treatment of diseases other than tuberculosis, which, while the death rate may not be as high, are still exceedingly common, in fact so common that they are accepted as inevitable and as a part of the lives of most individuals. Many a good, old-fashioned mother still entertains the notion that her children must pass through a recurring series of diseases, such as scarlet fever, diphtheria, chickenpox, measles, etc. It does not strike the average adult as unusual that he should suffer from typhoid fever, pneumonia, or Bright's disease. These have been accepted as diseases incidental to life, and must be taken with philosophic equanimity as they come in the category of ills to which flesh is heir. It does not strike the average human intellect that these common, everyday ailments can be classified equally with tuberculosis, with smallpox and other malignant diseases in the class of preventable diseases, and that if the death rate from them increases or decreases, such increase or decrease can be attributed to distinct underlying causes, either apparent or remote. As a matter of fact, some of these causes lie so close to the surface that they have been ignored. We shall endeavor to indicate how one of these causes has had a material influence in affecting the percentage of deaths from the diseases mentioned.

A study of the vital statistics of the United States throws some light on this interesting subject. Notwithstanding the strides that have been made within the past two decades, in sanitary science, in the practice of medicine and surgery, in the betterment of living conditions, and in the general improvement in the physical status of all classes of the population, it is nevertheless the fact that in only a few diseases has the death rate been lowered.

It was to be expected that with the prominence given to the study of tuberculosis, the means would have been found to reduce the annual number of deaths from that disease. The census of 1900 shows a gratifying decrease to 10,688 deaths from consumption, as compared with 12,146 deaths in 1890. Similarly, the valuable work done by the Straus' milk depots and kindred enterprises, the careful study that has been made of infant dietectics, together with the discovery of the diphtheria serum has materially reduced infant mortality throughout the country.

But if we study some of the other so-called common diseases, we shall find another condition of affairs. Not only has there been no decrease in the death rate, but, in spite of splendidly equipped hospitals, in spite of the development of medicine in every direction, in spite of the improvement of general conditions as cited above, the death rate of diseases which are most common, and from which the larger number of deaths result, has actually increased.

The following figures tell the story more plainly than words:

PROPORTION OF DEATHS FROM CERTAIN CAUSES PER 100,000 FROM ALL CAUSES.

| | 1900 | 1890 |
|---|---|---|
| Diseases with decreased death rate: | | |
| Cholera infantum | 2,401 | 3,260 |
| Diphtheria | 1,586 | 3,306 |
| Consumption | 10,688 | 12,146 |
| Diseases with increased death rate: | | |
| Pneumonia | 10,108 | 9,091 |
| Heart disease | 6,671 | 5,343 |
| Diseases of the kidney | 3,534 | 2,312 |
| Typhoid fever | 3,405 | 3,216 |
| Cancer | 2,837 | 2,203 |
| Apoplexy | 2,580 | 1,783 |
| Inflammation of brain | 2,470 | 2,113 |
| brain | 2,470 | 2,113 |
| Paralysis | 2,207 | 1,969 |
| Diseases of the stomach | 1,208 | 960 |
| Diabetes | 450 | 286 |

While some doubt may be thrown upon the accuracy of these figures, even with the errors that may arise from the lack of a uniform system of recording

deaths in all sections and communities, they are probably sufficiently correct to indicate a somewhat anomalous condition. It is difficult to realize our vaunted boast of progress in the last quarter of the nineteenth century; it is difficult to understand how we can claim for the 20th century a continuation of enlightened progress if the page of our vital statistics is to be marked and marred by a record of an increase of deaths from typhoid fever, a disease whose history and etiology are definitely understood; if we are to see pneumonia and heart disease gaining in virulence and in fatal power. If improved medical science, more healthful living conditions, more wholesome food, better sanitary regulations and a more tolerant industrial environment cannot explain the seeming inconsistency of an increased death rate, must we not look for another cause to explain this anomaly?

In our large cities to-day, and possibly in the smaller ones as well, certain difficulties arise in the medical treatment of all but the well-to-do classes, which are patent to the average practitioner. The demands which are made upon the majority of hospitals in large cities by so-called acute cases, are so great, that they must perforce discharge patients at the earliest moment that is consistent with safety, and with the prevention of a relapse. Again, physycians in private practice cannot reconcile their theories with the physical needs of their patients, who, by force of circumstances, must depend upon their daily wage for their daily bread. The average dispensary does not go into the highways and byways seeking whom it may cure; its connection with its patient ceases with the latter's failure to return for treatment.

The report of the Post-Graduate Hospital for the year 1904 shows that the average length of stay in the hospital was 17.2 days. In Roosevelt Hospital, in the same city, it was 19 days in 1903. In Beth Israel Hospital, 23.2 days. In Mt. Sinai Hospital, 20.79 days. On the other hand, the report of the German Imperial Insurance Department shows that the average stay of patients in sanatoria, suffering from diseases other than tuberculosis was 52 days for men and 56 days for women. It is interesting to note at this point, that under the German invalidity law, treatment in sanatoria is not a privilege but a right which even the lowliest workman has, and one which is freely granted to him when ill, in the hope of preventing subsequent invalidity, with all that it entails.

Irrespective of the form of medical practice, whether in hospital, dispensary, or private practice, it is obvious that as a result of the difficulties which confront the practitioner, we are developing a class of people in the community who may aptly be called the "half cured." They comprise the men and women whom the hospital discharges at the very beginning of convalescence because of lack of room, the men whom the private practitioner can no longer influence for their best good, for the reason that an impelling need drives them to the shop or to the factory at a time when nature is just beginning to let her handmaids, rest and sleep, exert their magic influence; the women who leave the maternity ward at the expiration of two weeks, because their children and their households require their urgent attention. All these and more make up the little army, not of incurable, but of uncured men and women who complain that their strength does not come back; who are always tired; who still have the pain in the back, or in the head, or in some other organ; who tell you that they are listless and indifferent, that they no longer have the same capacity for the daily task; these are the ones that tell you that they easily take cold, that they have trouble with the heart, that work has become distasteful, or that they cannot work. These are the ones that eventually drift to the relief agencies as permanent dependents, or who in time help to swell the mortality lists, and to increase the death rate from pneumonia and heart disease, and the long, ghastly list of ills which could be prevented if we but read the signs aright.

For let it be remembered that to-day we are beginning to recognize that diseases that were supposed to be the common heritage of all are in fact not so. It is the weak who succumb to disease, and not the strong. If pneumonia conquers, it is because an already weakened frame cannot resist the attack. The tubercle bacilli cannot live in a healthy organism, and the same will probably be found true of the cancer germ when it is once isolated. That a man is as old as his arteries, is an axiom of the earliest medical practice, and the heart that has been debilitated by acute illness will break if the time and the opportunity is not given it to restore itself to normal conditions. And so through the whole gamut of diseases, which so frequently result in death, and in which there has been an increase in the death rate during the last census decade, we will find that previous acute illness in the individual afflicted has left ineradicable weakness in the organism, by reason of the fact that insufficient time was allowed for a thorough and complete convalescence.

If we study the census statistics somewhat further we shall find another interesting series of figures, which, if they are not convincing, are at least indicative of the truth of the foregoing premises. The death rate from certain principal diseases in 1900 shows a remarkable dissimilarity in the number of deaths from pneumonia and nervous diseases in the large cities when compared with smaller cities and towns.

The following table will give some idea of what is meant:

DEATH RATE FROM CERTAIN PRINCIPAL DISEASES IN 1900 PER 100,000 OF WHITE POPULATION.

| | Pneumonia. | Diseases of the Nervous System. |
|---|---|---|
| New York | 320.2 | 175.6 |
| Chicago | 210.4 | 170.8 |
| Manhattan | 358.2 | 173.0 |
| Boston | 248 | 194.7 |
| Philadelphia | 231.7 | 254.6 |
| Buffalo | 151.7 | 162.9 |
| Johnstown | 308.9 | 244.3 |
| Hoboken | 287.2 | 282.1 |
| Albany | 175.3 | 281.8 |
| Allentown | 181.2 | 257.6 |
| Atlantic City | 136.4 | 282.1 |
| Davenport | 100.7 | 253.1 |
| Covington, Ky. | 126.1 | 311.6 |
| Portland, Me. | 210.8 | 387.4 |

Why is it that in large cities, and especially in Manhattan, the percentage of deaths from pneumonia should be so alarmingly high, and from nervous diseases so remarkably small? Surely it cannot be due to improper or insufficient treatment, since the local New York hospitals and medical practitioners are renowned above others for their skill and thoroughness. Nor can it be attributed to special climatic conditions producing diseases of the respiratory tract. If this were the case we should expect to find Portland, Me., vying with New York in the number of deaths from pneumonia, while the census figures show that Portland has the maximum number of deaths from diseases of the

nervous system. We should expect that deaths from diseases of this character would be found in the greatest number in a city like New York, where the daily struggle for existence on the part of all classes of people is at the greatest tension, and where nervous break-down is a common everyday occurrence. How can we explain the somewhat paradoxical occurrence that New York, of all cities, should have such a low death rate from nervous diseases?

I venture to give the following explanation, which, while it has no basis of statistical proof, will at least commend itself to thinking minds as rational and logical. In large cities neurasthenia and other nervous disorders are as common even among the classes of population who earn their livelihood by manual labor as in smaller cities. The daily grind of existence, the worry of finding sustenance for the morrow, the hand-to-hand struggle for the necessities of life set up changes in the nervous system which make the individual susceptible to minor ailments and which fill the clinics and dispensaries and hospitals. If these patients could be given the opportunity which is afforded their more fortunate brethren of a thorough convalescence, with all that this word conveys, there is no doubt that the majority would be restored to a condition of physical fitness which would enable them to withstand for long periods of time, future onslaughts of disease. Instead of such a happy state of affairs, we find conditions such as were stated above. Patients are discharged from hospitals as soon as they are able to walk. Practically no general hospital will receive so-called ambulant cases. It is a common experience to the social worker that admission is refused to sick people for the reason that they do not belong to the so-called "hospital cases." In other words, they do not require surgical intervention, or are not so acutely ill as to be bed-ridden. Again, to repeat for the purpose of emphasis what was said above, the number of men and women who return to work or resume daily occupations requiring hard manual labor and mental worry is legion. It is this class, unfit for work, physically incapacitated, and bodily weakened, who become the prey of diseases like pneumonia, consumption, heart disease, and Bright's disease. The man of wealth, or the man whose means are only moderately ample pursues a different course. Under the advice of his physician he travels to Europe, spends weeks in a sanatorium, hies himself to the country or to the mountains to spend weeks, and if necessary months, until his convalescence is assured, and his complete recovery an established fact. Can there be any doubt that if the wage-earner, less fortunate from the standpoint of wealth, could obtain similar treatment; if the honest, industrious workman, whose slender purse has been exhausted by his illness, could obtain the recreation, change, nourishment, and rest which are so essential for a thorough convalescence, that our census figures would show a startling diminution in the death rate from pneumonia and tuberculosis, and similar diseases?

The remedy is a simple one, and can be stated in few words. If our hospitals and dispensaries are unable to provide properly for the sick from the standpoint of time, if they must be discharged when they are technically cured, but still weak and impotent, additional institutions must be created to meet their needs. Whether they be called sanatoria, convalescent homes, or by any other euphonious title is immaterial. What is desirable is that they should approximate to the least extent the regulation hospital and to the greatest extent the normal home. If such institutions which will give opportunity for rest, change of environment, pure air, and the small amount of medical attendance, which may be necessary, can be built in cities, there is no valid reason why they should not be established there. It goes without saying, however, that for the purposes intended, the country adapts itself admirably.

Away from the city where land is cheap, a convalescent home should be built on the cottage plan, and should be conducted to approximate as closely as possible normal family life. Of equal importance, however, in effecting a complete cure of our patient, is provision for his family in his absence. We have heard much of the dangers of material relief and of the possibility of pauperizing families who may receive it. But there comes a time when we must cut the Gordian knot. It is better public policy, viewed from the standpoint of economy or any other, to make adequate provision for the man's family who is incapacitated by illness, and whose savings are exhausted, than by permitting him to return to work in an enfeebled condition, to sow the seeds of more serious illness, and probably bring into the world offspring puny and undersized.

Another plan which will command itself to many because of its simplicity, is the subsidizing of the patient himself by giving him the wherewithal to regain strength and health after a period of debilitating illness. If this is supplemented by relief for his family, we have almost an ideal method of caring for the convalescent. Its one disadvantage may be summed up in the fact that the average individual might remain in his original home environment during the time of convalescence. From the medical standpoint, change of surroundings is a valuable therapeutic aid, and one that should be taken advantage of by the poor as well as the well-to-do. In fact, for the former, unaccustomed to change of any kind, a different environment in many instances produces remarkable improvement in condition.

The value of the two forms of treatment has already been recognized by private individuals. The Winifred Masterson Burke Relief Foundation, instituted in 1902 by John M. Burke will, when it becomes fully operative, provide for establishing convalescent hospitals, and a fund for the relief of persons who have been self-supporting, but have temporarily become incapacitated by illness, and will furthermore provide temporary assistance for the families of individuals thus afflicted. I quote from the deed of trust, as it gives valuable information for similar enterprises which may be contemplated in the future. "The benefits of the foundation shall be reserved for intelligent and respectable men and women, who in consequence of sickness or discharge from hospitals, before they have regained strength sufficient to earn their livelihood, may be in need of temporary assistance." Under the deed of trust ample latitude is given to the trustees to administer the trust at their discretion, and the interest of the four millions of dollars, the principal of the trust fund, will unquestionably be a novel and important factor in the cure of disease.

Within the past year, the Loeb Memorial Home for Convalescents has been created in New York City, for the purpose of providing an opportunity for the enjoyment of wholesome surroundings in the country to recent sufferers from acute diseases, who have not yet recovered their strength sufficiently to attend to their daily duties. The trustees have purchased a farm in Westchester County, N. Y., on which it is intended to erect a cottage which shall approximate the home as nearly as possible. While there will be medical supervision, such oversight will be kept in the background as far as possible, so as to avoid to the greatest extent any suggestion of a hospital.

I have given these two illustrations to indicate what has been done by private benevolence. There is no doubt that they will act as an incentive to others to endow similar homes and funds. It is a question, however, in view of the prevalence of acute diseases, whether it is not the function of the State to consider the possibility of organizing some system of convalescent treatment for the sick among its citizens.

As a matter of public policy, most States in the Union have recognized the need of making provision for the insane, and in most communities there are general municipal hospitals for the treatment of acute and chronic diseases. More recently, States such as Massachusetts have recognized the needs of the tuberculous sick, and have established State sanatoria for their treatment. It is extending this theory a step further if provision is made for the convalescent either in State camps or in State homes, or by subsidy from the State treasury. Under present conditions there is probably no form in which public out-door relief would be less objectionable and less subject to abuse than if it was applied to the temporary care of the sick and of their families.

Sickness is a condition easily determinable by medical examination, and in the granting of relief to those who have passed the necessary examination, greater allowance could be made with less danger of pauperization than would be possible under a general out-door relief system.

Here, too, we would be applying a system already recognized in Germany, and one that has been in use for a number of years. The invalidity law of Germany, under which a fund has been established to which both the employer and employee contribute, practically guarantees to the latter, adequate treatment in case of illness, and relief of his family in the interval.

Such a compulsory law is probably impossible in the United States, but there is no reason why individual State government should not make similar provision for the sick, particularly as the compulsory tax which is demanded in Germany, is indirectly assessed under our system of government.

If it is true that the average human life is valued at $1,500, it is only logical to assume that an initial outlay that will preserve this asset to the community will be economic and justifiable. Surely it is wise for the State, for private philanthropy, or even for organized benefit societies, labor unions, etc., to institute a carefully regulated system of convalescent treatment, whether in specially adapted homes or not.

Such preventive medicine will in time eradicate the constantly growing need for homes for incurables, for hospitals and sanatoria for consumptives, for special institutions caring for the many forms of chronic diseases, and will accomplish what has not yet been accomplished, notwithstanding our undeniable progress in medical science. I need hardly repeat that I refer to the lowering of the death rate from diseases which are altogether too common, and which result from disease attacking a too weakened frame.

Let us give all classes of our population the opportunity of convalescing after acute illness, and we shall shortly find that we have developed a class of individuals better fitted for work and more competent to labor physically and mentally. And what is more important, physically, mentally, and morally fit to bring into the world children of sound and healthy minds, who will carry forward successfully the ideals for which this country stands.

## TREATMENT OF TYPHOID FEVER.

By D. E. ENGLISH, M.D.,

MILLBURN, N.J.

Having received more letters in regard to my treatment of typhoid fever* than it is convenient to answer, it has seemed to me better to republish a brief synopsis of that treatment.

When called to see a patient whose symptoms and history seem to indicate typhoid, although a positive diagnosis may not be possible at first, he is at once sent to bed, if not already there, and explicit directions are given to keep him absolutely at rest. He should not be allowed to raise himself up in bed to take food or drink, and the use of a bed-pan should be insisted on. It is just as well at this first visit to have him put in the sunniest, quietest, and best ventilated room available, and on a firm, smooth mattress. As to diet, he is to have nothing whatever until the next visit, except sterile water, or a little weak tea without milk. He is given ten to twenty, or possibly thirty, grains of calomel if he is still in the first week of the disease. This is to be followed in eight hours by half an ounce of magnesium sulphate. Where there is no reliable nurse the salt is often not given on the excuse that the bowels had already moved freely, so when the nurse is not reliable, it is well to give two compound cathartic tablets with the calomel, and not order the salts. A dose of a bromide may be ordered to be given after the bowels have moved, and the stomach has become quiet, in nervous or anxious patients. A blood culture is taken for purposes of comparison later on.

In cases where the patient is seven or more days from the initial chill when first seen, the large dose of calomel should not be given. Instead give calomel gr. ss., bicarbonate of sodium gr. iii, aloin gr. ⅛ and podophyllin gr. ⅛, at one dose, to be followed by calomel gr. ss. and bicarbonate of sodium gr. iii every half hour until eight doses have been taken.

At the next visit, twenty-four hours later, the diagnosis being now fairly clear, the patient is put on the special diet and treatment. If, however, the blood culture shows a malarial infection, the special typhoid treatment is deferred for three days while quinine is being given.

If a double infection is suspected the special diet is begun at once. The diet is as follows: Two ounces of Weir Mitchell's dissolved beef at 6, 8, 10, and 12 A. M., and 3, 5, 7, and 9 P. M. The white of one egg, acidulated, at 7, 9, and 11 A. M. and 4, 6, 8, and 10 P. M., allowing the stomach to rest between 12 and 3 P. M. and between 10 P. M. and 6 A. M. The patient is urged to take large quantities of sterile water at all times, either plain or slightly acidulated with lemon juice. The egg is prepared by stirring (not beating) the white of one egg in two and one-half ounces of sterile water, and adding five drops of dilute hydrochloric acid, or half a teaspoonful of lemon juice, preferably the acid. If the patient distinctly desires it, a litle sugar may be added. The beef is prepared as follows:

℞ Acidi Hydrochlorici (U. S. P.) ʒi.
Aquæ Destillatæ, ʒvii.

M. S. A teaspoonful to one pint of water for dissolving beef. Put one pound of finely-chopped beef into a one-quart glass fruit jar, add a pinch of salt and one pint of sterile water, shake well; then add one teaspoonful of the above prescription and shake again. Put the sealed jar in a cool place, like a cellar floor (not on ice) for

*Camphorated Carbolic Acid, Medical Record, Vol. 44, p. 426; Treatment of Typhoid Fever, ibid., Vol. 57, p. 1120; Diet, Drugs, and Diagnosis in Typhoid Fever, ibid., Vol. 62, p. 302; Typhoid Infection, ibid., Vol. 62, p. 1026.

twelve hours. Then set the jar into water, as in making ordinary beef tea, and keep it hot without boiling (about 110° to 120° F.) for four hours. Strain through two layers of cheese-cloth, wringing through all the juice. Flavor with salt and pepper, and serve agreeably warm.

No other food should be given before the end of the third week of the disease, when whole eggs, soft boiled or poached, or a little finely-minced meat, and later thoroughly cooked corn-starch and other starches may be cautiously added. No milk or toast should be allowed until after the patient is entirely well. These two things I believe to be the most harmful foods ever given in typhoid, and responsible for many deaths.

The most scrupulous cleanliness of the patient, and his bed, must be enforced. Cases of relapse are probably instances of reinfection either by the patient himself or by the nurse.

The special medicinal treatment is by the administration of a preparation, which for want of a better name, is known as "carbolated camphor," and is made as follows: To three parts of gum camphor add one part of crystallized carbolic acid, which has been liquefied by heat only. Let them stand, tightly covered, for forty-eight hours, then filter through absorbent cotton, and add a little more clean camphor gum. The object of this is always to keep the resulting liquid supersaturated with camphor, thus rendering it comparatively bland and unirritating to mucous membranes. While this mixture may be used with success when newly made, it is better to let it stand, tightly sealed, for two weeks before using. It is given by dropping the dose into a capsule at the time of administering. The dose is ten to twelve drops every two hours at first, skipping perhaps one, possibly two, doses in the night if patient is getting needed sleep. This dosage is kept up for from three to five days, according to circumstances, when the intervals between doses are lengthened or the amount given at each dose lessened. The indications for lessening the dose are the lowering of temperature and the altering of its regularity of curvature; the absence of exhausting diarrhea or tympanites; and evidences of cardiac depression. A bad effect on the kidneys need not be feared; sometimes an albuminuria will disappear under its use. Overdosing will manifest itself first by cardiac depression. This preparation will keep down the fever, prevent diarrhea, tympanites, and pain, and hasten the recovery of the patient.

Throughout the course of the disease the bowels should be kept freely open. This may be comfortably accomplished by giving every night, or second, or third night, a tablet triturate containing aloin gr. ⅛ and podophyllin gr. ⅛, with the addition from time to time of a little calomel and soda. How the carbolated camphor acts is a mooted question, but it probably serves to disinfect, to a certain extent, both the intestine and the blood, while the camphor tones up, or stimulates, the abdominal system of sympathetic nerves. Its use does not preclude the employment of nux vomica, strychnine, digitalis, alcohol, or other symptomatic treatment when indicated. It may be given close to the dissolved beef, but it is better not to give it within fifteen minutes but it is better not to give it within fifteen minutes of the acidulated egg. I believe, having tried both, that a patient will get well quicker, and with much less emaciation and exhaustion, under this treatment than under the expectant, or purely symptomatic treatment, with milk feeding.

A working man will be back at his work one week sooner on the average, and the mortality will not be over two per cent. in cases seen before the end of the second week.

---

**Some Surgical Observations on Referred and Reflected Pain.**—James Sherren states that by the term "referred" pain he means the result of stimulation of a nerve in its course, or, in some cases, to stimulation of one of the branches of the nerve, the pain being felt in the former, in the area distal to the point stimulated; while in the latter, it is felt in the whole cutaneous distribution of the nerve. The familiar injury of the ulnar nerve at the elbow giving rise to pain in the hand is an example of the former. The pain felt over the distribution of the trigeminal nerve when one of its branches is irritated is an illustration of the latter. By "reflected" pain the writer means pain localized to the surface of the body occurring in association with visceral disease, and perhaps with joint disease. An example of this is the pain felt in the right side of the abdomen in certain cases of appendicitis. He refers especially to referred pain which is the result of injury to a peripheral nerve, produced by an accident or during the course of a surgical operation. He declares that in cases of primary suture of an accidentally inflicted nerve wound, silk should never be used in suturing, on account of the difficulty of making these wounds aseptic and the ease with which silk becomes infected. In all cases of referred pain and cutaneous hyperalgesia following injury of a nerve in continuity, the treatment is the same. Operation should be performed and the injured part of the nerve removed. The ends should then be brought together and sutured. Referred pain may result from a surgical operation, and it may also arise from pressure, or from involvement of a nerve in disease, and lead to difficulty or error in diagnosis. These cases demand very careful examination, and undue attention should not be given to any one symptom.—*The Clinical Journal.*

**The Occasional Clinical Resemblance Between Caries of the Vertebræ and Lumbothoracic Syringomyelia, and the Location Within the Spinal Cord of the Fibers for the Sensations of Pain and Temperature.**—William G. Spiller describes a case of caries of the vertebræ recently under his care which presented the symptoms of lumbothoracic syringomyelia in so striking a manner as to make a diagnosis uncertain. The patient, a man twenty-three years old, began to have pain in the lumbar region and abdomen four months before he came under the writer's observation. The resemblance in this case to lumbothoracic syringomyelia consists of several features. In the first instance, there were scars on the abdomen which were the result of painless burns in childhood. Tactile sensation was preserved with almost complete loss of pain and temperature sensations in the lower limbs, although the degree of this dissociation of sensation varied when the patient was forced to rest in bed. When standing, the patient had extreme genu valgum which had existed about five years, and which closely resembled arthropathies. The patellar reflexes were slightly exaggerated and voluntary power in the lower limbs was slightly diminished. Careful examination revealed a very slight kyphoscoliosis. The patient fell down a flight of steps four months before death, after which he became completely paralyzed in the lower limbs. There was absence of signs of psoas abscess and of pulmonary tuberculosis before the accident, as well as absence of a pronounced kyphosis. The writer states, however, that this is not the only case of caries of the vertebræ without distinct kyphosis that he has seen. After the patient's death, microscopic examination of the spinal cord showed a tubercle in the right lateral column at the extreme lower end of the thoracic cord and involving the area of Gowers' tract. A little higher another tubercle was found in the left Gowers' tract. The writer thinks that this case seems to afford proof that Gowers' tract contains fibers of temperature and pain. He believes that tactile fibers—at least, in part—are in the posterior columns. The writer declares that he does not believe that tuberculous myelitis is a common complication of caries of the vertebræ, but this case and another previously described by him prove that it may occasionally occur.—*University of Pennsylvania Medical Bulletin*

MEDICAL RECORD.

*A Weekly Journal of Medicine and Surgery.*

New York, October 28, 1905.

## IS PNEUMONIA INCURABLE?

"PNEUMONIA is a self-limited disease, which can neither be aborted nor cut short by any known means at our command," is the sentence which opens the section on the treatment of lobar pneumonia in one of the most popular of American textbooks of medicine. Reading this, one need not be surprised to learn from an article in the *American Journal of the Medical Sciences* for June of the present year that 533 cases of pneumonia out of a total of 991 treated in the hospitals of Philadelphia, terminated fatally. Whether this mortality of over 50 per cent. is regarded as a justification for the pessimistic belief of the medical authority quoted, or as the result of a do-nothing policy born of the acceptance of his despairing utterance, will depend upon the therapeutic faith or lack of it of the reader. Of course, these figures do not fairly express the real mortality of pneumonia, for the hospitals receive the most desperate cases—the old, the social wrecks, those broken down by excesses of all kinds, by exhausting labor, and by privations, and the actually moribund—but even the commonly accepted mortality of 15 per cent. is one that brings reproach to the therapeutic art. Consumption is called "the great white plague," but pneumonia in its season is the champion killer. From October 1, 1904, to March 4, 1905, the mortality from consumption in Chicago was 11.4 per cent. of the total mortality, while that from pneumonia was 18 per cent., an excess of 49 per cent. of pneumonia over consumption. Is this dreadful waste of human life inevitable? or is it a direct result of the nihilistic teaching of authorities who are grounded in the doctrine of "self-limited" diseases, and doggedly refuse to listen to the assertions of others, as acute in observation and as honest in purpose as themselves, who claim that medicine is not powerless in the face of this devastating disease, and that pneumonia has been and often can be cured without waiting for the crisis on the seventh or ninth day? Let us hear the testimony of some of these competent observers that Osler and others so incontinently throw out of court.

The pathogenic organism of lobar pneumonia is admitted to be the pneumococcus or *Micrococcus lanceolatus*. It is possible, and probable, that other microorganisms, such as the influenza bacillus and various streptococci, may cause a disease indistinguishable from that excited by the pneumococcus, but such cases are exceptional and may be ignored in the present review. The pneumococcus is omnipresent and is found, we might say almost constantly, in the secretions of the mouth and throat of seemingly healthy persons. What endows it with special virulence in certain cases—whether a temporary depression of the resisting power of the individual or the stimulus supplied by the synergetic action of some other microbe—we do not know. This is a matter which it is to be hoped competent investigators, perhaps the Pneumonia Commission of the Health Department of New York, will take up and elucidate. However tenacious of life this microbe may be under favorable conditions, we know that it is exceedingly vulnerable. In sputum, moist or dry, it preserves its vitality for a long time, nineteen to fifty-five days in different experiments, but in cultures it soon dies. Its long life in sputum may be attributed to the protection afforded by the albuminous envelope, for F. C. Wood has shown that when the dried sputum is pulverized the contained pneumococci perish in from one to four hours, even when kept in the dark, and in about one hour when exposed to the sunlight. Given a microbe, which perishes so quickly under adverse conditions, growing in culture in the accessible alveoli of the lungs, it ought to be a comparatively easy matter to arrest its growth. And so it would appear to be, if we are willing to accept the testimony of those who have to deal with the disease in actual practice. It is commonly said the mere fact that many remedies are vaunted as being of service in the treatment of any disease affords sufficient evidence that a real remedy does not exist. This is doubtless true in some cases, but it may also indicate that the disease is so easily curable that it yields to various methods of treatment. Pneumonia is one of these diseases, and into which category one would place it—whether of the incurable or the easily curable—must depend upon the character of the evidence presented.

In the olden days—in the first half of the last century—bleeding was the accepted treatment for pneumonia. This has gone out of fashion, in the treatment not only of pneumonia but of all other diseases, and it is unlikely that it will be adopted again, although not a few of the present generation of practitioners regret its disuse. According to the imperfect statistics accessible to us, the mortality of pneumonia at the present day is greater than it was when venesection was in vogue, but whether this is because, as is asserted, the type of pneumonia has changed, or because bleeding was really curative must be left to conjecture. Another remedy for the disease, now equally out of fashion, but the beneficial effect of which many men still living in this city have witnessed, was the exhibition of a single large dose, 20 to 30 grains or more, of calomel. This was the routine practice of the late Dr. George P. Cammann and of his pupil Dr. James R. Leaming. Very many country practitioners, who do not lose many of their patients from pneumonia, rely almost as a routine measure upon diaphoresis in the management of their cases of this disease. The patient is put to bed surrounded by hot bottles, and is frankly sweated day and night, until the disease subsides, which it does often without waiting for the classical crisis. The details of this method were given by Dr. MacArtney of Fort Covington, N. Y., in the MEDICAL RECORD of September 19, 1896. Another mode of treatment for which its advocates—Dr. Simon Baruch and others

whose authority cannot be questioned—claim ideal results, is the cold pack. In a recent communication (Medical Record, September 23, 1905) Dr. Baruch states that he has lost but two patients, both practically hopeless from the beginning, in over 100 cases treated by this method. Dr. Andrew H. Smith a few years ago reported the successful employment of chloroform inhalations in the treatment of pneumonia, and commenting upon this article and a letter on the same subject by E. J. Whitehead, Dr. E. F. Wells of Chicago, recalled a report by Baumgartner (Lungenentzündung, Stuttgart, 1850) of 201 cases treated by himself and others with but 7 deaths, a mortality of 3.5 per cent. Chloroform inhalations were also commended by the late Dr. Roberts Bartholow.

The use of sodium salicylate has been warmly advocated by A. H. Smith, and the efficacy of this remedy was further insisted upon by Sebring in an article in this journal for April 22, 1899. The value of creosote, by inhalation in vapor or internally in the form of the carbonate, has been asserted so many times and so positively by trustworthy observers that it can hardly be disputed—yet it is ignored by most of the authors of textbooks on medicine. In the Medical Record there have been articles dealing with this method of treatment by Beverley Robinson, Leonard Weber, W. H. Thomson, I. L. Van Zandt, and others, the force of which can be denied only by impugning the credibility or the powers of observation of the writers. Another remedy which has been strongly advocated by Dr. H. Altshul is iodide of potassium in large doses. Dr. Altshul's article in the Medical Record for March 26, 1904, was in the nature of a preliminary report, and we have not seen any notice of further experiences with the remedy, but the account of its action then given would seem to warrant further trial. Quinine in enormous doses has also been given with apparently beneficial effect. Galbraith reports (*Journal of the American Medical Association*, January 28, 1905) fifty cases of pneumonia treated by quinine without a single death, and commenting upon this in the same journal for March 11, 1905, Solomon Solis-Cohen instances a case in his own practice in which a man with all the signs of pneumonia took by mistake 60 or 80 grains of quinine in the course of six or eight hours and promptly recovered. In what way these and other agents, such as digitalis and veratrum viride, exert their beneficial, if not curative, action in pneumonia, is beyond our purpose to discuss here. Some are doubtless microbicidal, others may be antitoxic, while still others probably have an opsonic action, but the essential fact is that they are regarded as curative by many acute and careful observers.

This review of some of the methods employed with a greater or lesser measure of success in the treatment of pneumonia is necessarily very imperfect. We have referred to only a few papers appearing in this journal, and one or two others, and have not drawn upon the immense literature of the subject as presented in other medical periodicals. But the testimony, such as it is, is all in support of the contention that something can be done in the way of aborting or curing pneumonia. It is true, men are not so ready to report their failures as their successes, yet that is no reason for rejecting positive testimony such as has been presented time and again in medical periodicals. There may be a fallacy underlying all these claims, but it behooves those who would dispute them to discover the fallacy and disprove the claims before giving utterance to ex cathedra statements regarding the absolute refractoriness of pneumonia to therapeutic endeavor. It is possible that all these presumably competent observers are wrong, and that they have happened upon a series of favorable cases in which the result would have been equally felicitous if they had followed a purely expectant treatment—but it is not probable. Those of our readers who have had the patience to follow us must, we believe, admit that there is at least some ground to hope that those are right who content that pneumonia is sometimes amenable to treatment. If they are right, then the dictum quoted at the beginning of this article is wrong, and a blind acquiesence in its hopeless teaching can but result in a deplorable sacrifice of human life.

## SCIENTIFIC RESEARCH.

In all the civilized countries of the world, scientific research has taken a foremost place as a means of increasing medical knowledge. Germany is undoubtedly the country in which patient and laborious investigation into the mysteries of medicine is carried on most successfully. France, however, has produced many men who have contributed largely to the elucidation of scientific problems, especially of those in which chemistry has played the chief part. Great Britain, on the whole, has lagged behind in this branch of medicine, although so far as research work in tropical medicine is concerned, she has more than held her own. The United States has, perhaps, more than any country, progressed in scientific research, and judging from the vast sums which have been provided for this purpose, and from the wealth of material and the quality of the men engaged, her advance should be yet more rapid in the future.

At the inaugural address of the winter session of the London School of Tropical Medicine, delivered on October 11, by Professor G. H. Nuttall, F. R. S., in the theater of the school, Royal Albert Dock, the subject of scientific research was ably dealt with. Professor Nuttall, a distinguished alumnus of Johns Hopkins University, and now of Cambridge University, England, pointed out that experimental medicine was responsible for the greatest advance which had been made in our knowledge of the cause, prevention, and cure of disease. The speaker laid especial stress upon the necessity of endowing research, and said that "all who were engaged in teaching and research had met with men capable of research and often had been forced to see them drift away into other fields of activity, too often from mere lack of means to offer them encouragement." He went on to show that laboratories alone do not constitute research, the investigators themselves must be men of capacity and well trained, and able to give their whole time to the work, and not be men "deep versed in books and shallow in themselves." The best teachers were those who were also investigators, but this combination required so much time that it was almost impossible to perform any other duties.

Professor Nuttall severely criticised the inadequacy of research and hygienic laboratories in Great Britain, and stated that at Oxford and Cambridge no provision existed for research or even for proper teaching in hygiene. The speaker concluded an instructive address by an eulogy of the London School of Tropical Medicine and by advice as to the need of patience in research emphasized by the undue haste in publication which had characterized certain investigators, both in England and in other countries.

### The Alleged Protozoön of Scarlatina.

Considerable interest was aroused not long since by Mallory's description of certain protozoön-like bodies which he had observed in the epithelial cells and the lymph spaces of the skin taken from patients who had died of scarlet fever. He had been unable to find these in the living patient. This discovery was hailed as a possible contribution to the etiology of the disease, and a number of investigators have since then busied themselves with the question along the lines indicated by Mallory. Duval obtained similar bodies from the blisters of scarlatina cases, and now C. W. Field (*Journal of Experimental Medicine*, Vol. VII, No. 4), has published the results of his investigations dealing with a similar condition not only in scarlet fever, but also in measles and other skin rashes. Field comes to the conclusion, based on an extensive series of observations, that the bodies described by Mallory are part of the protoplasm of the epithelial cells, which has been so changed in its chemical nature that its staining reaction differs from that of the surrounding protoplasm. The small round extra-cellular bodies found in the living patient may arise from degenerating cells, but this origin the author does not assert without reserve. In sections of control and normal skin, the nuclei of the epithelial cells were often seen to be indented by the cell protoplasm, giving them an appearance similar to those indented by Mallory's bodies. It would seem that if these bodies were protozoa, they would have been found in the sections from both the living and the dead skin of scarlatina and measles patients, as they were present in the blister fluid. Their occasional absence seems more suggestive of a degeneration than of a living organism. This view is also borne out by the fact that in one instance they were not found immediately after death, but were present in another specimen from the same case removed 24 hours later. Another circumstance of interest that apparently supports the idea that bodies found in the blister fluid are the products of degeneration and cytolytic activity, is the fact that these were found in the antitoxin rashes as well as in those of scarlatina and measles. Field's observations demonstrate quite clearly that a great majority of these protozoön-like bodies arise from degenerating cells and the differentiation between one of the latter and a true protozoön by the morphology and the staining reaction alone will remain a difficult matter. Although it would seem from these facts that the bodies described by Mallory may be what Field claims them to be, nevertheless they may be specific accompaniments of these diseases, and even if we cannot ascribe to them any pathogenic characters, it may yet be possible that their demonstration will prove of some asistance in the diagnosis of these cases.

**Phthisiophobia.**—The *Pall Mall Gazette* says that a great epidemic of imaginary consumption has prevailed in Paris since the close of the recent Tuberculosis Congress in that city.

## News of the Week.

**Medical Society of the County of New York.**—At the one hundreth annual meeting of this society, held October 23 in Hosack Hall of the New York Academy of Medicine, the following officers were elected: *President*, Floyd M. Crandall; *First Vice-President*, Walter Lester Carr; *Second Vice-President*, William H. Park; *Secretary*, John Van Doren Young; *Assistant Secretary*, J. Milton Mabbott; *Treasurer*, Charles H. Richardson; *Censors*, Henry S. Stearns, C. G. Coakley, James E. Newcomb, H. Seymour Houghton, and Egbert Le Fevre.

**Reciprocity Between New York and New Jersey.**—At a meeting of the committees of the two State Licensing Boards held at Trenton, N. J., on October 16, an agreement was adopted to the effect that after January 1, 1906, each State should recognize the certificates of medical examinations of the other.

**Alvarenga Prize of the College of Physicians of Philadelphia.**—The Alvarenga prize for 1905 has been awarded to Dr. Chalmers Watson of Edinburgh for his essay entitled: "The Importance of Diet; an Experimental Study from a New Standpoint." The next award of the Alvarenga prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about One Hundred and Eighty Dollars, will be made on July 14, 1906, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award. Essays intended for competition may be upon any subject in Medicine, but cannot have been published. They must be typewritten, and must be received by the Secretary of the College on or before May 1, 1906. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its ouside the motto of the paper and within the name and address of the author.

**Award of King Humbert's Prize.**—The international prize of 2500 lire offered by King Humbert I, of Italy, for the most valuable work on discovery in the domain of orthopedic surgery has been awarded for the first time to Dr. Oskar Vulpius, Professor of Orthopedics in the University of Heidelberg. The award was made in recognition of Professor Vulpius' achievement in the treatment of paralysis, and especially for his book entitled "Tendon Transplantation and Its Applications in the Treatment of Paralysis." Prof. Vulpius has presented the sum to a Bavarian home for cripples.

**Another Consumption Cure.**—A curious story comes from Williamsport, Pa., to the effect that a young woman of a neighboring town has been rescued from apparently inevitable death from pulmonary tuberculosis by swallowing the hearts of two rattlesnakes. The remedy is a traditional one in the family, and half a dozen cures effected in this way in different members, beginning fifty years ago, are recounted with much circumstantiality. It is essential that the hearts be still pulsating when swallowed.

**Catskins as a Remedy.**—The father of an eight-months infant in a little California town recently had to be threatened with arrest before he would consent to abandon his own peculiar form of treatment and allow a physician to be called.

The infant, dying of meningitis, was found wrapped in catskins, which the parents explained they had applied in order to give it the benefit of the electricity. Over fifty catskins were discovered about the house, the father having depleted the entire neighborhood of felines in his efforts to procure the necessary amount of electrical energy.

**Harlem Hospital Ground Sold.**—Property on the north side of East 120th street, used by the Harlem Hospital and by the city as a pier for the Randall's Island ferry, has been sold by the estates, which have owned it for many years. Large frame buildings, formerly private residences, occupy most of the plot and are tenanted by the Harlem Hospital. The lease by the city of the land used for the pier expires next February.

**Vermont State Medical Society.**—At the closing session, of the 92d annual meeting of this association held at Burlington on October 12, 13, and 14, the following officers were elected: *President*, Dr. M. L. Chandler of Barre; *Vice-President*, Dr. E. S. Albee of Bellows Falls; *Secretary*, Dr. George H. Gorham of Bellows Falls; *Treasurer*, Dr. B. H. Stone of Burlington; *Auditor*, Dr. J. H. Blodgett of Saxtons River.

**Colorado State Medical Society.**—The annual meeting of this society was held at Colorado Springs on October 3, 4, and 5. The following officers were elected: *President*, Dr. H. G. Wetherill of Denver; *First Vice-President*, Dr. E. T. Boyd of Leadville; *Second Vice-President*, Dr. Perry Jaffa of Trinidad; *Third Vice-President*, Dr. C. A. Ringle of Greeley; *Secretary*, Dr. Melville Black of Denver; *Treasurer*, Dr. S. E. Solly of Colorado Springs. The next convention will be held in Denver, beginning the first Tuesday in October, 1906.

**Chesire County (N. H.) Medical Association.**—At the annual meeting of this society held at Keene, N. H., on October 10, the following were elected as officers: *President*, C. W. Harrington of Peterboro; *Vice-President*, Dr. J. D. Proctor of Keene; *Secretary* and *Treasurer*, Dr. C. S. Walker of Keene.

**Thurber Medical Association.**—The fifty-second annual meeting of this society was held in Milford, Mass., on October 12. The following officers were elected: *President*, N. W. Sanborn of Bellingham; *Vice-President*, Dr. O. C. B. Nason of Medway; *Secretary*, Dr. A. J. Gallison of Franklin; *Treasurer*, Dr. C. B. Hussey; *Librarian*, Dr. C. D. Albro of Milford.

**Norfolk and Portsmouth Medical Society.**—The annual meeting of this society was held at Norfolk, Va., on October 10, and the following officers were elected: *President*, Dr. L Lankford; *Vice-Presidents*, Dr. B. R. Kennon and Dr. C. T. Parrish; *Secretary*, Dr. C. J. Andrews; *Treasurer*, Dr. E. T. Hargreaves.

**Mississippi Valley Homeopathic Medical Association.**—At the meeting of this organization, recently held at Watertown, Ia., the election of officers resulted as follows: *President*, Dr. H. E. Hoefle of Davenport; *Vice-President*, Dr. H. W. Wilson of Rock Island; *Secretary and Treasurer*, Dr. R. E. Peck of Davenport.

**Yellow Fever.**—At New Orleans the epidemic is apparently in its last stages, and in several days lately no deaths at all from yellow fever have been reported. Dr. White, October 17, ordered that no more patients be taken to the emergency hospital, and it was closed on October 22. At Panama also the disease is entirely under control, and the official reports state that the entire Isthmus is now free from the disease.

**Vital Statistics of Philadelphia.**—For the week ended October 21 the number of deaths reported to the Philadelphia Bureau of Health was 398, an increase of 30 over the number reported for the previous week, and 18 more than the number reported for the corresponding week of the preceding year. The largest number of deaths was due to pulmonary tuberculosis—42; the next largest to heart disease, 40; the next to nephritis, 39.

**"The Transvaal Medical Journal."**—Under this title the second medical journal of the Cape Colony makes its initial appearance. The object of the new publication is stated to be to supplement its older contemporary especially in providing each month an extensive résumé of current European and American work, and in fostering observation of the rich clinical and pathological material afforded by the colony.

**Site for New Missouri Sanatorium.**—A site of 190 acres in the Ozarks in the southwestern county of Lawrence has been selected for the new Missouri State Sanatorium for Tuberculosis.

**Dr. George B. Johnston** of Richmond, Va., has accepted the chair of surgery in the University of Virginia.

**Naval Inspector Frank Anderson**, for several years in charge of the U. S. Naval Hospital at Yokohama, has reported for duty at Mare Island, San Francisco, where he will have charge of the medical supplies.

**A Garden of Medicinal Plants.**—About a year ago, Dr. Rodney H. True, in charge of the medical plant investigation of the U. S. Department of Agriculture, had assigned to him ten acres of land in the Golden Gate Park, San Francisco, to use for the cultivation of medicinal plants. The result is an exceedingly creditable garden not only for the study of these plants, but for demonstration that these useful weeds can be profitably cultivated along the Pacific Coast.

**A Tuberculosis Hospital at San Francisco.**—San Francisco is to have a new hospital for tuberculous patients at the alms house, and an isolation hospital, or pest house, at Thirty-seventh and E streets.

**The Western Surgical and Gynecological Association** will hold its next meeting at Kansas City, Mo., December 28 and 29, 1905.

**Generous Gift to Hospital.**—The Lancaster (Pa.) General Hospital has received a gift of $10.000 from Mrs. Mary L. Baer, to endow a free bed in memory of her husband.

**Gifts to the Sydenham Hospital.**—At the last meeting of the Board of Directors of the Sydenham Hospital, Mr. Wm. I. Spiegelberg, the president, announced the following donations: Meyer Guggenheim's sons presented $5,000 to endow a bed in memory of their late father; Mr. Isaac Guggenheim personally presented $2,800, and in addition Mrs. Isaac Guggenheim obtained $700 for the Maternity division; Mr. Samuel Lee Schubert donated the use of the Lyric Theater and arranged a benefit performance for November 26, 1905.

**Construction of a New Hospital.**—The contract for building the proposed Catholic hospital at Taylorville, Ill., has been let for $18,058. It is believed that the hospital will be finished on or before February 1, 1906.

**Vacancies for Physicians at Indian Agencies.**—The United States Civil Service Commission announces an examination on November 22, 1905, to secure eligibles from which to make certification to fill a vacancy in the position of physician (male) at $1,000 per annum, San Juan Indian Agency, N. Mex.; another, at $900 per annum, at Fort Bidwell, Cal., and similar vacancies

as they may occur in the Indian Service. Applicants must be between the ages of 25 and 55 years. The examination is open to all male citizens of the United States who comply with the requirements. Applicants should at once apply to the United States Civil Service Commission, Washington, D. C.

**Biographs of Epileptic Seizures.**—Dr. W. P. Spratling, of the Craig Colony for Epileptics at Sonyea, has been trying for several years to secure a series of living pictures of various types of epileptic seizures. Dr. W. G. Chase, of Boston, spent a month at the Craig Colony recently, and, at his own expense, made living pictures of a large number of epileptic seizures from start to finish. The results are so satisfactory that the seizure is pictured on the screen in the minutest detail, the patient's breathing and the movements of the eyeball being easily distinguished. Pictures of other pathological conditions, such as hemiplegic gaits, nystagmus, etc., were made as well. The pictures will be shown at the next meeting of the National Association for the Study of Epilepsy, etc., in the Academy of Medicine, New York City, on the evening of November 29 next.

**Opening Exercises of the Wisconsin College of Physicians and Surgeons.**—This college opened its thirteenth year September 19, when the introductory lecture was delivered by Dr. Albert W. Myers. Dr. G. H. Bassett has been appointed Professor of Histology and Pathology, with Dr. Newton Wason as his assistant. Drs. G. Frederick Shimonek and Arthur Ritman have also been added to the faculty.

**American Academy of Medicine.**—The thirtieth annual meeting of this organization will be held in Chicago November 9 and 10, 1905. Committees will report on medicinal practice act, taching of hygiene in the public schools, and the collegiate degree. Ten papers have been promised for this meeting, exclusive of reports of committees and the President's address.

**Chicago Medical College an Integral Part of Northwestern University.**—It is said that steps are being taken for the purpose of making this medical school an integral part of Northwestern University. The governing board of the medical school has been instructed to turn over to the University trustees the $350,000 special endowment of the former.

**Chicago Gynecological Society.**—The twenty-seventh annual meeting of this Society will be held at the Auditorium Annex October 20, at which there will be a business meeting, to be followed by the election of officers and a banquet. The guests of the Society on this occasion will be Drs. Hunter Robb, of Cleveland, Ohio, and Matthew D. Mann, of Buffalo, N. Y.

**Tri-State Medical Association.**—The Tri-State Medical Association of Mississippi, Arkansas, and Tennessee will hold its twenty-second annual meeting at Memphis, Tennessee, in the Hotel Gayoso, on November 21, 22, 23, 1905. Information concerning the meeting may be obtained from the secretary of the association, Dr. Richmond McKinney, Memphis Trust Company Building, Memphis, Tennessee.

**Obituary Notes.**—Dr. Wellington G. Beyerle died at Reading, Pa., on October 16, at the age of seventy-four years. He was graduated from Jefferson Medical College in the class of 1852. During the Civil War he served as surgeon to the 141st Regiment, Pennsylvania Volunteers.

Dr. John H. Dickenschied died at Plover, Lehigh County, Pennsylvania, on October 17, at the age of eighty years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1847.

Dr. Upton A. Shorretts, formerly of Frederick, Maryland, died at Colorado Springs, Colo., on October 8, of pulmonary hemorrhage, at the age of forty-eight years. Four years ago declining health compelled him to remove to Colorado Springs. We was graduated from the Hahnemann Medical College, Philadelphia, in 1883.

Dr. Harry D. Hull, of Adrian, Michigan, one of the oldest practitioners of the town, is dead. He was graduated from the Bellevue Hospital Medical College, New York, in 1877.

Dr. Joseph Huyett, of Milan, Ill., said to be the oldest physician in Illinois, having practised for fifty-seven years, died at his home, aged eighty-five years. He was surgeon of the Ninety-third Illinois regiment in the Civil War. He was graduated from the Jefferson Medical College, Philadelphia, in 1843.

Dr. John A. McKenzie, of Halifax, N. S. died of appendicitis on October 11, at the age of forty years. He was a graduate of the College of Physicians and Surgeons of Boston, and had been assistant superintendent of the Nova Scotia Hospital, Mount Hope, since 1892. For a number of years he was demonstrator of anatomy at the Halifax Medical College, resigning the position about a year ago.

Dr. Orin Peak, of Oak Park, Ill., and the earliest physician of that suburb, is dead. He was born in 1826 in Bethel, Vt., and became a teacher to the Choctaw Indians in 1846. In 1854 he graduated from the Medical School of the University of Michigan. In 1864 he was appointed surgeon of the Twentieth Wisconsin Volunteer Infantry. After the war he settled in Oak Park.

Dr. John O. McReynolds, of Elkton, Ky., died on October 6, at the age of seventy-eight years. He was graduated from the Jefferson Medical College, Philadelphia, in 1849, and was for many years a member of the State Board of Health and also County Health Officer. His two sons are Dr. R. P. McReynolds, of Philadelphia, and the Hon. J. C. McReynolds, Assistant Attorney General of the United States, Washington, D. C.

Dr. Frank Buller of Montreal died on October 11, at the age of sixty-one years. He was widely known in both Canada and in this country as an ophthalmic surgeon of unusual skill. He studied medicine at Victoria College, Cobourg, and was graduated from there in 1869. He was also the holder of a degree from McGill. After obtaining his degrees, Dr. Buller went abroad and spent seven years in study at different universities. In 1876 he returned to Canada and commenced practice in Montreal. For seventeen years he was ophthalmic and aural surgeon at the Montreal General Hospital, afterwards resigning his positions to take up similar posts at the Royal Victoria Hospital. After his arrival in Montreal Dr. Buller became connected with McGill University, first as lecturer, and in 1883 he was appointed professor of ophthalmology and otology, maintaining the chair until the time of his death.

Dr. Lowell Holbrook of Putnam, Conn., said to have been the oldest practising physician in Connecticut, died October 16, at the age of eighty-seven years. He was graduated from the Medical School of New York University in 1849, and served as surgeon of the Eighth Connecticut Volunteer Infantry during the Civil War.

# Correspondence.

## VON BEHRING'S REMEDY FOR TUBERCULOSIS.

To the Editor of the Medical Record:

Sir:—Immediately before sailing from Europe for the United States I came in possession of the full text of Prof. E. von Behring's communication to the Congress of Tuberculosis in Paris on the 7th inst., in which he describes his remedy for tuberculosis. I find this to coincide in all essential particulars with a remedy for the treatment of tuberculosis introduced by myself, the nature and mode of preparation of which I first communicated to the American Climatological Association on May 2, 1897, in an article which appeared in the transactions of this Association, and likewise in the *Therapeutic Gazette* for that year. From the text of Prof. von Behring's communication it appears that his alleged discovery consists in so preparing tubercle bacilli that the immunizing curative substance contained in them is made available for absorption by the living tissues. For this purpose he finds it essential to remove from the tubercle bacilli certain substances by extracting them with water and chloride of sodium solution and then with alcohol and ether, after which the tubercle bacilli are powdered, when they are ready for subcutaneous injection.

From my publications referred to, and numerous others which have been made by me since, it will appear that I likewise remove certain substances from the tubercle bacilli by washing and extracting them with water, and then with alcohol and ether; and while I at first omitted the use of chloride of sodium solution as a second step, I have since found that the mucoprotein substance which binds the tubercle bacilli together, and causes their cohesion in mass, is more readily soluble in a chloride of sodium solution than in water, and have since resorted to its use. I have, however, not deemed it necessary to make a supplementary publication of this fact, because the protein substance referred to is also soluble in water and can be removed by prolonged washing upon a percolator, and the use of a chloride of sodium solution is therefore not an essential step in the preparation of tubercle bacilli, to the end that the immunizing substance contained within their bodies may become available.

As in von Behring's procedure, my next, and the most essential, step consists in extracting the tubercle bacilli with alcohol and ether, a process which, so to say, "unlocks" the tubercle bacilli by removal of the fatty, waxlike substance which they contain. After this they are reduced to an impalpable powder, and the immunizing curative substance becomes available for absorption by the living tissue, when injected subcutaneously; or for further extraction with distilled water, if the immunizing substance is to be isolated in its pure form.

From the foregoing it will appear that the method of preparation of Prof. von Behring's new remedy is identical with my own, up to and including the final reduction of the tubercle bacilli to a fine powder, where he stops. In my own work I have, however, gone further, in isolating the immunizing or curative substance by extraction in distilled water, until the tubercle bacilli yield nothing more and have become an inert mass.

In addition, I have accumulated and published my large clinical and experimental researches during the past eight years, showing that the remedy has immunizing and curative properties of a high degree of efficiency in the treatment of over 1,500 patients by myself at the Winyah Sanitarium, Asheville, N. C., and of a much larger number of patients by other physicians, with results which yield about sixty per cent. of lasting arrest of the disease, and recoveries in all stages of pulmonary tuberculosis. Still unpublished records of my work with this remedy further confirm its value, showing that the blood serum of patients after being treated with it, acquires and maintains marked antibacterial properties, and a high power of agglutination for living tubercle bacilli.

In view of the attention of Prof. von Behring, as well as that of other writers to my work, I herewith claim von Behring's discovery of a new remedy for tuberculosis. I must confess my astonishment at his apparent lapse of memory of the fact that I had the honor of personally relating to him my clinical and experimental experiences with my remedy, and of describing to him its method of preparation, on the occasion of my visit to him at Marburg in June, 1902. He was then pleased to manifest some interest and to ask me for reprints of my publications, which I sent to him after my return to the United States, about a month after our interview.

Dr. Karl von Ruck

Asheville, N. C.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

THE OPENING SESSION—INTRODUCTORY ADDRESSES—A MEDICAL AND SURGICAL EXHIBITION—OBITUARY.

London, October 6, 1905.

The opening of the schools is, of course, the chief medical event of the week, and something of the old enthusiasm for the first of October (this year the second, on account of Sunday falling on the first) as "our opening day" remains, although the time-honored introductory lecture has been supplanted by other forms of celebration at several hospitals. Still we have a number of schools faithful to the tradition, and here are a few notes I have gathered from the addresses:

At University College, Professor H. R. Kenwood started with the statement that the object being to prevent as much as to cure disease, keeping persons in health rather than prescribing for them should occupy the first place in the consideration of the medicine of the future. By the development of a sanitary conscience in the community and the employment of protective agencies, much of the communicable disease we see should be gradually reduced and eventually wiped out. Bacteriology had built up such a record that we are warranted in expecting it is destined to become in the not very distant future a tremendous force in the prevention of disease. But hygienic reform must depend almost entirely for its success on the proper education of the people, for at the present time it is estimated that about a quarter of a million persons are suffering from phthisis, and this is only one form of disease which it is hoped the future will suppress.

At the Middlesex Hospital, Dr. R. A. Young took for a subject, "Method in Medicine," and method, he said, was "a means of transit," or, as expressed by Sir William Hamilton: "All method is a rational progress—a progress towards an end." Referring then to the influence of the analytical and methodical mind of Bacon upon the advancement of science, he considered method in relation to medicine (1) as it affected teaching and study, (2) in regard to research, (3) as applied to the practice of medicine. Teaching and study might be considered together, since teaching should only be control, direction, and guidance. The education and refinement of the senses, particularly sight, hearing, and touch, and the formation of sound judgment from the information thus obtained, were of paramount importance. The present-day danger was to forget that the patient was the end of study, and disease his condition—not a concrete entity. Practically no great principle had been evolved without years of methodical investigation, even of effort which long appeared fruitless. But the manner in which work was done enabled the profession. Therefore, the lecturer urged the students to work in no spirit of maudlin sentimentality, not puffed up with elation about the nobleness or beneficence of their art, but with senses alert and sympathies awake to do their best.

At St. George's Hospital, Mr. Brudenell Carter, referring to the recognition of women in the profession, said the time had come when medical matters concerned their mothers and sisters as well as "the mere man." Looking to the anxiety that was expressed about the competition of Germany in various fields, he said they were handicapped by one fact—that Germany had banished smallpox from her territory by the proper application of an English discovery, while we still permit that disease to levy tribute of lives and money, to attack thousands, and to condemn those whose lives are spared to blindness, disfigurement, or permanent debility which may be handed down to future generations. It is the problem of a medical school how best to establish effective barriers against disease, how best to deal with the admirable raw material of English homes with the definite object of producing men and women who should be conversant with disease in all its manifestations, and be wise counsellors in those wider questions of conduct of life which lie at the root of national efficiency. The great problems of life and society were problems of health, habits, and physical environment, and only the medical profession was capable of enlightening the public on these subjects. This was a task for which the clergy, statesmen, and politicians had shown themselves inadequate.

At Charing Cross Hospital, Sir J. Crichton-Browne remarked that twenty years ago one of their staff, Mr. James Cantlie, uttered a warning about physical deterioration, and, though that was neglected and sometimes ridiculed, we had heard much of it lately. The outcome of much talk of it left it a mooted question whether the race were deteriorating, or regenerating, or merely standing still. There were defenders of each hypothesis, but there was certainly a deplorable amount of deterioration around us, and inefficiency abounded. Hordes of undergrown, underfed men,

women, and children were inefficient. Many public institutions were as incompetent as stenosed valves of a damaged heart. Education was inefficient, or there would be less ignorance, stupidy, and hooliganism. Our economic system, our municipal administration, the army, and so on, were all arraigned by the lecturer and inefficiency pronounced widespread. Passing on to the temperance question, he declared that in nearly 90 per cent. of inebriates they began early, from fifteen to twenty years of age; and he urged that it was "bad form" to take alcohol before reaching their majority.

At King's College, Professor Clifford Allbutt gave the address, and, as seemed appropriate in an institution devoted to all branches of education, argued that the problems and difficulties of our London medical schools could only be solved on principles common to education everywhere and always. Education, he said, must always consist of two parts—the earlier, drawing forth and refining of all the faculties, and such a formation of them as habits that a right reason and virtue became easy and pleasant; the latter, the adaptation of these faculties to particular callings. It was of general education that the values, methods, and ends were less well understood. It was by ideas that the world had grown. To be deficient in ideas meant to be in bondage to convention, and to defects of adaptability and foresight. The protection of the public from inefficiency in its physicians was not the concern of a university, but of the state. Education was not only from ignorance to knowledge, but also from evil to good. The professor exhorted the students to seek the higher life, which was the greatest good in practice as in spirit, and to believe the words of Socrates, that the "unprobed" life was not worth living.

At St. Mary's Hospital, Dr. Wilfred Harris dilated on the competition of schools and the grievances of practitioners. He said that while the entries of students in the London schools decreased, their financial difficulties increased; and the action of the King's fund in refusing to assist those hospitals which continued to eke out their failing resources had brought matters to a crisis. Some schools were appealing to the public, but success in such appeals would injure the cause of medical education. The failing entry was partly due to the difficulty of obtaining a London degree through want of systematized teaching and restrictive regulations. Endowment of medical education Dr. Harris pronounced an unfortunate necessity. Further to attract the better class of students, the conditions of practice must be made more attractive by the removal of those grievances which bore so hardly on the majority of practitioners. The three most important were (1) unqualified practice and quackery, (2) hospital abuses, (3) contract medical practice. The public needed protection against quacks as much as against fortune tellers.

Mr. Gerald Balfour delivered the address at the Medical Faculty of the new University of Leeds. He said that he spoke as a mere outsider, he said that the medical profession was not only worthy of honor but was to be envied. In what other profession did they find science so happily blend in one harmonious whole? It was said of the golden age of science; it had made more progress in the last two generations. He spoke not only of the wonderful mechanical applications of science to everyday life; he thought rather of the great intellectual conquests, which had created new sciences, he might say new points of view involved in every department of knowledge. The extreme of energy in various forms of matter, of physics. Let them also consider the profound modification in our conception as to the construction of man. In the advance which science had made, medicine had not lagged behind. A young man who entered into its pursuits at such a time as this was to be envied.

At the Women's School, Mrs. Bryant said the ideal of study was most usefully conceived, not as a scheme of learning to be achieved, but rather as growth out of the primitive intellectual interests of human beings. With the growing mass and complexity of human knowledge the demand for specialization in studies ran ahead of self-improvement. The specialist who lost interest in events outside his work lost something of his humanity. To the complete student the two ideals, theoretical and practical, seemingly contrasted at first, appeared as parts of one, each helping to develop the other, each necessary to the other, as science to art and art to science.

At other schools and some of these dinners, conversazioni, etc., replaced the lecture, and in proposing and responding to the toasts there was, I hear, a "very free supply of frothy eloquence." Next week all will have settled down to steady work.

A "medical and surgical exhibition," organized by the *British and Colonial Druggist*, was opened on Monday, and closes this evening. It was held in the Horticultural Hall, and was very largely attended. A good feature was that it was restricted to medical men and their friends. Invitations were sent to all members of the profession within a radius of twenty miles. On the tickets it was stated they were not transferable. A covering letter requested those who could not use the ticket to return it. Thus the exhibition was very select. Between fifty and sixty manufacturers sent exhibits, the majority from London, but the United States were also represented.

A sad death was that of Colonel E. V. MacSwiney, Army Medical Staff, who on Tuesday, when traveling from London to Birmingham, opened the carriage door while the train was going at high speed and disappeared. A fellow passenger saw the tail of his coat and tried to take hold, but failed. The colonel was well known and popular at Birkenhead and Liverpool, where he was principal examiner on the medical staff for embarkations, and did important work for the transports which left for Mersey during the war. He was on leave until November on account of health. He received his commission in 1868.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

MANILLA, Sept. 7, 1905.

From the beginning of the outbreak of cholera, August 23, 1905, until to-day, September 7, 1905, there have occurred in the city of Manila 146 cases, of which 121 ended fatally. The early cases were most virulent in character, and the victims succumbed in a few hours. The first fifteen or twenty cases were of the cholera sicca type; then came a series of more or less atypical cases, and now the disease has assumed the ordinary diarrheic form described in the textbooks and has become more mild in character.

The disease has been widespread throughout the city of Manila, but no two cases occurred in any one house. One noteworthy feature of the disease has been that the sections of the city which were most affected during the epidemic of 1902-'03 have been but slightly involved this time. This is very curious, because they have been considered the most insanitary in the city.

The Filipinos and Spaniards are vigorous in their opposition to being removed to the hospitals, and object to leaving their homes, and at the present time are putting every obstacle in the way of the health officials toward isolating cases. If this continues it is difficult to see when a cessation of the disease may be expected. So long as each case can be removed to the hospital, and the premises thoroughly disinfected, there is not much danger from its spread. The natives, however, object to going to the hospital, and in order to avoid it they hide their sick. During the past few days many dead bodies have been found which were removed from the place at which death occurred. That is probably done to avoid disinfection of the premises. It can thus be seen that many centers of infection remain undisinfected, and, in consequence, are a great menace.

No land quarantine has been used this time, and the results up to the present time have fully justified this course. The disease has not spread to the provinces nearly so rapidly as during the former epidemic. The total number of cases reported from the provinces has been 92, which is very much less than the number of cases which occurred during the corresponding period of the previous epidemic. So far the disease has all occurred within a radius of fifty miles of Manila.

The measures, in general, have been much less harsh than formerly, and with the exception of the objection to going to the hospital, the natives have cooperated much more freely this time than from previous occasions.

The outbreak in Bilibid Prison has not yet been controlled. In all, there have been, in that institution, thirty-five cases and twenty-nine deaths. The condition was considered so grave Saturday, September 2, that the Governor requested the Commissioner of Public Health to assume charge of the sanitary conditions of the prison. Vigorous measures to combat the epidemic were at once instituted, and since that time there has been a decided falling off in the number of cases, and it is hoped that the disease will be entirely under control within a few days.

Dr. Richard P. Strong, the Chief of the Biological Division of the Bureau of Government Laboratories, is at present engaged in vaccinating the inmates of the prison with anticholera vaccine of his own preparation. The plan is to vaccinate one half of the number of prisoners in each squad, and if there is any further cholera in that institution it will be interesting to observe whether the vaccinated prisoners remain free.

The starting point of the disease still remains a mystery, and until this is definitely ascertained it will be impossible

to decide where the infection came from. The opinion is gradually gaining ground among medical men that cholera is endemic in the Philippines, and that outbreaks must be expected from time to time. The present plan is to remove all cases to the San Lazaro Hospital, which is a fully-equipped and modern institution in all respects. Trained nurses and physicians are in attendance, and there are facilities for giving the best possible care to the unfortunates. Of the thirty-eight patients admitted to the San Lazaro Hospital, twenty-three are still alive, so that it will be seen that the death rate, so far, has been much less than for outside cases.

## CHRONOPHOTOGRAPHY TO FURNISH MATERIAL FOR THE LABORATORY AND CLINIC.

To the Editor of the Medical Record:

Sir:—The purpose of this letter is merely to suggest the application of the moving picture projecting apparatus as an adjunct to the present method of teaching the science of medicine and surgery. Besides being equally interesting and instructive if offers an excellent opportunity to follow more closely the instincts of humanity as well as economy, which should at least invite an opening for conviction. C. Francis Jenkins of Washington, inventor of the first successful moving picture projecting apparatus, says: "Thousands have been entertained and amused by moving-picture exhibitions, have laughed at the vigorous osculations of the 'Widow Jones' and have felt the excitement of a realistic fire scene. But the Phantoscope and its rivals have a more serious mission than that of reproducing, however vivid, trivial and familiar happenings."

In the Clinic: The management of a normal case of labor, from the first visible presentation to the delivery of the placenta, once recorded on a film, could be reproduced on the screen as many times as desired. Any step not clearly understood by the student would be recapitulated without the slightest deviation. Rare complications in childbirth having once appeared before the camera, would become an ordinary occurrence before the class. The various steps in the different methods of amputating, reducing fractures and dislocations; the different plastic operations, etc., could easily be demonstrated with each particular lecture. The famous operations and methods could be performed in every clinic at the same time, by the authors. Would not it be wonderfully interesting to witness an operation personally conducted by one of the famous surgeons of the past? Think how interesting the picture records of operations personally conducted by the famous men of to-day would be to posterity! By showing the characteristic gaits in locomotor ataxia, spastic paraplegia, paralysis agitans; and the convulsions in epileptic and hysterical subjects, the neurologist would afford the student a rare opportunity to become very familiar with the differential diagnostic points. Death or change of residence may at any time deprive the clinic of its most typical case. But with a moving-picture record of the subject such unfortunate happenings would not involve a loss to clinical instruction. The ophthalmologist, by operating close to the camera, could reproduce each step in the strabismus, enucleation, or keyhole operation, greatly magnified; thereby giving the class in general a more satisfactory view than the few who may be fortunate enough to have select positions near the field of the original operation. There are many other uses for such apparatus in the clinic which no doubt will occur to the mind of every reader, so it will not be necessary to continue with this phase.

In the Laboratory: By making a moving-picture record of the capillary circulation, through a microscope, one frog would furnish material enough to last several years. This is practically the only method by which the correct idea could be portrayed on every retina alike. One poor little cur would have nine times as many deaths as nine cats, and still have one more life left with which to demonstrate the physiology of the breathing apparatus. The guinea pig or rabbit, after having been inoculated with a particular bacillus or drug may die; but the characteristic symptoms could be recorded on a film and reproduced without needless sacrifice. Aside from the humane standpoint, the addition of a moving-picture outfit to the laboratory would mean economy. Material is abundantly supplied in some colleges while in others the reverse is true.

Nearly every college has a projecting lantern outfit to which could be attached, for little additional expense, a moving-picture mechanism. Should an accident destroy one of the positive records it would mean a delay of a few days only until another could be made from the negative. Any person familiar with an ordinary projecting lantern manipulation could easily learn the necessary points to give a satisfactory moving-picture exhibition. The writer is preparing to make some picture records, and hopes to demonstrate the same in the very near future.

Arthur G. Bretz, M.D.,

Binghamton, N. Y.

## Progress of Medical Science.

*Boston Medical and Surgical Journal, October* 19, 1905.

**Sugar in the Cerebrospinal Fluid of Diabetes.**—A preliminary report on this subject is made by N. B. Foster, whose first observation was made on fluid obtained by lumbar puncture in an adult male with symptoms suggesting a fulminating cerebrospinal meningitis. The fluid was found to be fermentable with yeast, yielded phenylglucosazone crystal, and was dextrorotary. The small amount of fluid handled confined the quantitative testing to the reading of the sacchrometer, which was 2.5 per cent. The patient's urine contained four per cent. of sugar. Foster has also examined the cerebrospinal fluid of twelve other diabetes and has found sugar in every case, the percentage ranging from one-half to three. He expresses himself as unable to draw any inference from the amount present. The author briefly describes the techniques of his analyses. He has no therapeutic or other suggestions to make on the basis of his findings, and hopes that others will continue the analyses, as the matter is certainly an interesting one.

*New York Medical Journal, October* 21, 1905.

**The Sanatorium for Tuberculous Patients and Its Medical and social mission.**—S. A. Knopf decrys the silly ideas which have crept into the minds of many people regarding possible dangers from the proximity of tuberculosis sanitoria, and shows that they do good, not only to the patients housed in them, but also have a beneficial effect on the sanitation of surrounding communities. Residence in such an institution teaches the patients how to care for themselves, and they become, when they return to their own families, missionaries of good hygiene. Moreover, the modern institution does much for its patients in the line of educational benefits—as lectures, schools for children, music classes, etc. The sanatorium movement gave the impulse to the antituberculosis movement, through which the rich have come closer to the poor, the educated closer to the uneducated, while the kind-hearted have roused the interest of the indifferent. All have united their efforts to combat a common foe.

**A New and Simple Method of Performing Rectal Valvotomy.**—The method of L. J. Hirschmann is thus described: The patient is placed in the knee-shoulder position and a large operating proctoscope inserted after the sphincter has been prepared for it by either gradual dilatation or by immediate divulsion under local anesthesia. A ligature carrier (figured in the paper) is threaded through the eye at the curve with a rubber ligature (5-8 French); the ligature passes inside of the curve of the needle and should project about half an inch from the point. The needle, which is nine inches long and has a handle bent at an angle, so as not to obstruct the view, is then passed up around and hooked through the highest offending valve until the point is projected and the ligature can be clearly seen. This end is then grasped by means of a long forceps and the ligature is pulled through until it is outside the proctoscope. The needle is then passed back and around the edge of the valve and is brought down also outside the proctoscope, and is then taken off the ligature. The ligature is now in place. Over the ends is slipped a lead fastener or large perforated shot, the ligature being put on the extreme stretch, the shot is grasped and pushed up to the valve tightly by means of long compression forceps and firmly compressed. This puckers the valve and constricts it in such a way that circulation is shut off and the ligature sloughs through in from two to eight days. After the ligature has cut through, the edges retract so that a large V-shaped opening is left, which gradually still further retracts. The author claims for this method the following advantages: (1) No anesthesia is required; (2) it does not require over ten minutes; (3) requires but few instruments; (4) the patient is not confined to bed; (5) no stitches are required and there is no hemorrhage; (6) the rubber ligature, being soft and non-irritating, does not scratch or bruise the bowel *in situ* or during its expulsion, and there is no danger of its doing damage if it should by any possibility be carried up higher into the bowel.

**Epileptogenic Myopathic Kyphoscoliosis.**—W. P. Spratling reports (with photographs) three cases of this rare muscular deformity due to epilepsy. He shows how convulsions may lead either to death by asphyxiation, or paralysis, due to post-convulsive exhaustion. The latter condition is temporary, usually disappearing in the course of a

few days, and is usually confined to an isolated group of muscles, an arm or a leg, though it may be general enough to constitute a hemiplegia. Physical accidents as the result of convulsions are very common. Finally, one may have the myopathic kyphoscoliosis, the special topic of the author's paper. In his case there was, as shown by the photographs, a decided leaning or "slouching" of the body to one side or forward. The fingers were flexed on the palms and the wrists flexed at right angles. The leg muscles were not affected. Electrical reaction was altered in the shoulder and back muscles in each case. In all three faradic response was diminished in the trapezius, latissimusdorsi, supra- and infraspinatus. Galvanic response in the same muscles was diminished and sluggish, though there was no reversal of formula. A distinct flattening was noticeable over the parts affected. The pathogenesis of the condition is found in a localized cortical cell destruction in part, confined to the area that is most involved during epileptic convulsions. Grand mal attacks of the most rigid and uncompromising type only can produce it. The first step in its establishment is in the nature of a postconvulsive exhaustion paralysis, and, did the central lesion stop at this point, the condition would soon pass away. But it becomes emphasized under repeated attacks until the integrity of the cortex at the point of the repeated discharges is damaged beyond repair. Like other forms of paralysis due to organic lesions, the condition once fully established is practically incurable. Passive exercise and the use of electricity may help to lessen atrophy and retain some use of the affected parts.

*Medical News, October 21, 1905.*

**Antitoxin for Poisonous Mushroom Intoxication.**—W. W. Ford presents a preliminary communication on this subject. The literature of mushroom poisoning is briefly reviewed. The fatal cases practically always follow the eating of one special species of plant, the white or deadly amanita. Those following ingestion of amanita muscaria are practically never fatal, for an efficient antidote to the muscarin is found in atropine. The author's experiments have been made with the amanita phalloides, which he finds in abundance in the woods around his city (Baltimore) and in the Blue Ridge Mountain region. The fungi were dried in the sun, macerated in water, and the mass filtered. There resulted a thin, brown fluid, the toxic principle of which is known as phallin, which has a very destructive effect on the red cells of man and all the common animals. Following the injection of fatal quantities subcutaneously, there is in both rabbits and guinea pigs an extensive subcutaneous edema with hemorrhages in the lymphatic glands, in the serous membrane, and in the internal organs, especially the liver and kidney. The heart always stops in diastole, and the blood may be fluid if the dose has been large. Death occurs usually within four or five days, although it may occur after the lapse of two or three weeks, owing, probably, to degenerative changes in the liver and kidney. If rabbits be treated with repeated small doses of phallin subcutaneously, followed by large doses intraperitoneally, it is possible to immunize them against the action of multiple toxic doses. The mortality among animals so treated is very great, but successful results have been thus far obtained with five or six rabbits. These animals were eventually able to withstand the injection of about five times a fatal dose and their blood serum exhibited definite antihemolytic and antitoxic properties. The experiments of the author are being continued on other animals.

**The Bacterial Treatment of Sewage and Its Adaptability to Small Communities.**—R. F. Palmer notes that we have in certain of the non-pathogenic bacteria living agents capable of increasing rapidly under favoring conditions and capable, furthermore, of changing dead animal and vegetable matter into oxidizable compounds. This great natural force should be utilized in the disposal of waste matter. All of the substances found in ordinary sewage contain C. H. and O. in varying proportions, while many of them contain N. Whether the sewage be emptied into a stream, on land, or on artificial beds, the means of its final disposition is the same. Through the action of these saprophytic bacteria the hydrogen and oxygen recombine to form water and the carbon becomes carbon dioxide: nitrogenous matter is broken down and, combining with oxygen and alkaline bases, forms ammonia, nitrates and nitrites. The author then alludes to the various common methods of ultimate disposal and describes the methods of preparing contact beds or intermittent filters, continuous or trickling filters, and septic or precipitation tanks. A more detailed description follows of the disposal plant at the Geological Survey Camp at Roosevelt, Arizona. Disposal of sewage by bacterial treatment is to be urged where it is possible, for this method practically eliminates all danger of contaminating the subsoil and the effluent which eventually escapes from the sewage-bed system to the neighboring stream or pool is practically harmless. Such effluents, containing as they do large numbers of nitrifying bacteria, will considerably improve an already polluted stream.

**A Study of the Results of Abdominal Hysterectomy for Fibroids of the Uterus with and without Drainage.**—J. Brettauer details his experience in fifty-four cases, all of which recovered. Of this number thirty-two were drained with gauze through the cervix, while twenty-two were not drained. The author's operative methods are described in full, and the individual symptoms of the series as pulse, temperature, gastric disturbances, intestinal reaction, pain, etc.—are analyzed. He finds that in the two sets of cases, those drained and those not so treated, there was not, generally speaking, the slightest difference in the immediate post-operative course. He had previously employed drainage more for the purpose of controlling the small amount of oozing, than for actual drainage; during this time a few instances occurred where a retroperitoneal hematoma formed and became infected after the removal of the gauze form the cervix. This complication, though not of any serious consequence, was always unpleasant; to-day, therefore, it appears preferable to him to sew up the stump in all cases, so as to assure a more perfect hemostasis.

*American Medicine, October 21, 1905.*

**Etiology and Prevention of Smallpox.**—W. T. Councilman gives the results of an investigation of smallpox, undertaken by members of the Pathological Department of the Harvard Medical School. It is believed that the organism which constitutes the virus of vaccinia and smallpox is the same; that in vaccinia it undergoes a definite cycle of development, resulting in a structure, the gemmules arising from simple growth and segmentation; that in smallpox a further and more complicated cycle of development, in which probably sexual forms occur, is added to the vaccine cycle. It is only in man and in the monkey that the conditions are favorable to the development of the cycle which constitutes smallpox. The intranuclear parasites are just as characteristic for smallpox as are the cytoplasmic forms of vaccinia. They are found in both variola inoculata and in variola vera. The spores which arise from the multiplication of the intranuclear bodies constitute the contagion of smallpox, which is capable of air transmission. This introduced into a susceptible animal, develops the typical disease, smallpox, both cycles of the organism taking place in the lesions. In the non-susceptible animal, such as the calf or rabbit, only the single, and probably asexual cycle is developed, constituting vaccine. The work, which is nearing its temporary conclusion, has left the fundamental questions relating to the disease unanswered. These relate to: (1) The parasite and its complete life cycle. (2) The relationship between vaccinia, variola inoculata, and variola vera. (3) The mode of infection in variola vera. (4) The mode of production of the exanthem. (5) The immunity, its mode of production, and the relationship between the natural and acquired immunity.

**Scheme for the Sanitary Control of the Municipal Milk Supply.**—George W. Goler advises the establishment of a bureau of milk inspection, of which the chief sanitary officer is the head, and through whom licenses are issued for the vending of milk in the city. Boards of physicians and scientists appointed by medical societies should compile rules for the production and distribution of milk of higher nutritive value and lower bacterial content than ordinary good city milk. They should directly, or through the inspectors of the bureau of milk inspection, or through inspectors appointed by the commission itself, insure: (1) Character of stable and feed of cattle, health of milkers and care of utensils. (2) A negative tuberculin test. (3) A bacterial standard, not greater than 10,000 bacteria per cubic centimeter. (4) A nutritive value of 12½ per cent. solids, of which 4 per cent. must be fats. The necessity for the organization of the milk work for a municipality under one executive head having the license power cannot be too strongly emphasized, for by this means only may the producer and the vender be under sanitary control. When such laws are enacted for any municipality as will make it an offense punishable by fine or imprisonment to bring milk into the city that has not had the seal of sanitary approval set upon it, and everything with which it comes in contact, our children and ourselves, will no more be exposed to the dangers that arise from dirty, disease-bearing milk.

**The Identity of Variations and Modifications.**—Charles E. Woodruff calls attention to the fact that none of the current theories of heredity will satisfactorily explain the pathological and anomalous conditions which the physician sees every day, but which the general biologist never studies, as he deals mostly with the healthy. The biologists are diametrically opposed to each other in some of their statements of what are apparently facts. They have con-

sidered some differences as hereditary variations due to an inherent power of the organism to vary, while others consider all these differences to be acquired, that is, modifications due to the environment and yet transmissable. As so many of man's anomalies do not come under either definition, it is suggested that there is no difference between variations and modifications, the two classes being merely artificial classifications with no basis in fact. Each is due to causes acting either early or late, as the case may be, and each is hereditary as long as the causes last, generation to generation. Indeed, there is often no way of determining whether a given anomaly is a variation or an acquired modification. Transient heredity is the term suggested for those cases where an organism is modified for some generations and then returns to the normal. Some changes can be permanent, as when they are due to an actual chemical change in the germ protoplasm. Neither school of biologists can be right if the other is wrong, and the general trend of opinion is in the direction of considering both right, and that some missing links will cause a compromise. It is pointed out that in biological theories of every sort, whether in the matter of heredity, the origin of variations, the origin and explanation of life, regeneration, and indeed every biological problem now discussed, there is a curious tendency to look upon living protoplasm as a complex inert chemical, having no innate powers of its own, but merely reacting to the multitude of forces impinging upon it. As it cannot vary of its own accord, it is merely modified. The constant tendency of every organism then is to be normal if it is only permitted. Herein lies the possibility of freeing society of its degenerates by finding out what causes them, and then removing the causes. The whole trend of modern thought is in this direction, not only of students of the lower classes, but of physicians also. It is a complete overthrow of the idea that these cases are happening without cause, and it throws out much hope for the future of the race.

*Journal of the American Medical Association, October 21, 1905.*

**The McGraw Ligature.**—A. J. Ochsner reports his experience with the McGraw ligature since December, 1902, when he saw the method demonstrated by its inventor. He has used the method 156 times and has come to the following conclusions: "1. Anastomosis with the McGraw elastic ligature can be accomplished in a satisfactory way (a) between stomach and intestines; (b) between intestine and intestine. 2. The opening can be made any desired length. 3. It can be made without carrying infectious material from the lining of the stomach or intestine to the peritoneum. 4. It can be performed quickly. 5. It requires no special skill or ingenuity. 6. The patient shows very little, if any, shock after the operation. 7. The patients are relatively very free from pain, and can usually sit up in bed with the aid of a headrest a few hours after the operation. 8. The method should not be employed in making a pyloroplasty. 9. It should not be used in making a cholecystenterostomy."

**Periodic Paralysis.**—G. E. Holtzapple refers to the literature of this subject and gives an interesting account of a family of which he had the record for four generations and had observed for twenty-two years. Seventeen of the members of this family had the typical periodic paralysis, six of them dying in an attack. A number of others were sufferers from migraine. The attacks were of the characteristic type, the severer ones involving all the muscles except those of the face, eyes, tongue, the organs of speech and deglutition, and the rectal and vesical sphincters. Others were more or less permanently crippled by the disease. The pathology of the condition is discussed, the author being inclined to consider it as a vasomotor neurosis affecting the blood supply of the anterior horns, which are supplied almost wholly by the anterior spinal artery. The slow progressive permanent paralysis which occurred late in life in two of the cases reported, he thinks is due to slow degeneration of these horns from the frequent disturbances of nutrition. The paralysis in these cases seems to him to be closely allied to the local paralyses accompanying migraine, and thinking that there might be an active toxin from the gastrointestinal tract at work he made careful urinary examinations in six of the paralytic cases, in three of those suffering from migraine, and in five of the healthy members of the family. The average quantity of urine voided in all and the average output of urinary solids appeared to be the same. There was, however, a noticeable difference in the nitrogen elimination in the paralytic individuals and in these directly after the attacks. It appeared that these patients do not excrete the normal quantity of nitrogenous metabolic products. It will require further observations to determine the exact degree of relationship, if any, between the diminished urea excretion and the paralysis. With the idea that the attacks were due to a vasomotor spasm he resolved to try large doses of bromid, preferably of potassium, 5ss. with one or two grains of citrate of caffein repeated in one or two hours. This gave decided relief, and helped to abort the attacks; small doses were never tried.

**Uterine Fibromata.**—T. B. Eastman argues against the probability of the harmlessness of uterine fibromata. He reviews rather extensively the literature of the degeneration of these growths and gives results of his own observations, reporting briefly six cases illustrating the difficulty of diagnosis of pathologic conditions other than the tumor itself. In one of these the patient was not even aware that she had a tumor, much less a degenerating one. He protests against the idea of waiting in these cases for the menopause to effect a cure, and thinks, with the low death rate of hysterectomy and the fact that so many of these growths are undergoing dangerous pathological changes which cannot be diagnosed prior to operation, that all fibromyomata should be removed unless there are concurrent conditions rendering the operation inadvisable.

**After-Effects of Diphtheria on the Heart.**—F. W. White, from a study of seventy-eight cases of diphtheria with heart complications, after their discharge from the Boston City Hospital, and kept under observation for from five months to a year, and in none of which was there any evidence of heart disease antedating the diphtheria, deduces, in substance, the following conclusions: 1. The cardiac disturbance after diphtheria usually presents the picture of a mitral insufficiency with irregular heart action and few symptoms. Occasionally there is only rapid pulse or cardiac irregularity alone. 2. Moderate disturbance of the heart is common after diphtheria, and in many cases persists for from two to six months after the original illness. 3. Frequently the cardiac lesion does not clear up in the first half year, but lasts much longer; some patients recover; others probably do not. The duration of the heart trouble is usually in proportion to the severity of the original illness. 4. The fact that only few heart symptoms are often present after diphtheria should not mislead us as to the importance of the injury to the heart. 5. Cardiac disturbance of long duration after diphtheria may be entirely recovered from, and hope should not be given up in individual cases. 6. The treatment of the condition consists in a sufficient period of rest in bed, and then in watching the effects of mild exercise on the heart for several months at least and grading it to meet individual requirements. White hopes to follow up his cases still farther, and, therefore, considers his paper as a preliminary report.

*The Lancet. October 14, 1905.*

**Nitrite of Amyl in Gynecology.**—C. F. A. Morse reports the use of this remedy in two cases. Case I was that of a woman from whom bilateral parovarian cysts had been removed, and where symptoms in the next few hours suggested the occurrence of secondary hemorrhage. The wound was reopened and the truth of the suspicion verified. Inhalations of amyl nitrite greatly improved the patient's condition, and in a few minutes the pulse had changed from a condition of apparent hopelessness to one of promising vigor, a gauze plug having in the meantime been applied locally. Ultimate recovery ensued. The patient appeared to be the subject of hemaphilia. Case II was one of internal hemorrhage due to ruptured extrauterine pregnancy, and gave equally good results with those obtained in the first case.

**A Method of Sterilizing Sponges.**—F. W. Andrewes extols for this purpose the use of a solution of persulphate of ammonium. The mixture is made as follows: 37 grammes of the persulphate are dissolved in 950 c.c. of pure distilled water and 11 c.c. of strong hydrochloric acid are then added. At first the mixture is not strongly germicidal but it increases in this respect in a few days. It should stand at least four days before use, but not more than a month. It is cheap and efficient. This method does not do away with the necessity of preliminary mechanical cleaning of the sponges required for the removal of all fibrin and other organic matter in their interstices. When thus ready the sponge becomes sterile after one hour's soaking in the solution, which is clear and colorless, does not stain, and has no injurious action on the skin, though it may fix blood stains in the crevices of the nails.

**Toxic or Typhoid Pneumonia.**—Notes of a case are given by A. M. Elliot, whose patient was a strong, wiry man, about 35 years old, and employed in the hospital ward in the care of pneumonia cases. The original diagnosis was lobar pneumonia, but in a few days the question arose whether it was not a case of typhoid fever, as the abdomen was tympanitic and bowels loose, though the Widal test was negative. On the seventh day of the illness an acute attack of arthritis came on in the left shoulder joint. This fact suggested pneumonia again rather than typhoid fever. On the tenth day there was a pseudo crisis, but no true crisis occurred, and the illness continued. On the twenty-third day, owing to indications of fluid in the chest, the patient was tapped. Four days later the temperature had become normal but rose again and fluctuated for a

week longer. In the meantime pus was found in the chest and a rib was resected. Later he had an acute cystitis and an acute dysentery but finally recovered, having been in the hospital for nearly three and a half months. Throughout the disease there was an increased leucocytosis. Pneumococci were found in the blood and in the chest fluid and pus, in the latter mixed with other cocci. The pneumococcus was found also in the urine. The author looks on the case as one of acute toxemia, caused by the Fraenkel organisms.

**A Case of Divers' Disease.**—The report of the case is made by W. H. White and F. A. Bainbridge. The patient was a man of 38 years, suffering from the usual symptoms of the malady common to divers the "bends" or transient paresis being a prominent feature. He was under observation for a period of years and finally was readmitted to hospital for cough and weakness in the legs. Death occurred in about nine weeks. Autopsy showed cirrhosis of the liver and advanced tuberculous changes in both lungs. The main interest centers about the condition of the central nervous system in view of his original malady. The brain and spinal cord were removed from the body about twenty-four hours after death and they appeared normal to the naked eye. The cord was hardened for six weeks in a mixture of 3 per cent. bichromate of potassium and 10 per cent. formalin; pieces from different levels of the cord were imbedded in paraffin. The staining methods used wese those of Marchi and Weigert Pal; anilin blue-black was also employed. The white matter showed no morbid changes either by Marchi's method or by the Weigert Pal method. Throughout its entire length the periphery of the white matter presented a vacuolated appearance; this was due, however, to postmortem changes. As regards the gray matter, a large number of sections from different parts of the cord were examined; many of them were cut serially. They appeared to show that the cells in the lumbar region were fewer in number than usual; the deficiency was most marked in the case of the large cells of the anterior horns. The cells which were present looked healthy, the only exception being that some who saw the sections thought one or two cells showed slight necrosis. The perivascular spaces in the lumbar region were larger than those in the thoracic or cervical regions. Since sections from all parts of the cord were treated in precisely the same way, the larger perivascular spaces in the lumbar region could not be due to shrinkage of the vessels. There was definite thickening of the small arteries in both the gray and the white matter; the patient had been a drinker. No hemorrhages were observed.

*British Medical Journal, October 14, 1905.*

**Pulmonary Atelectasis in Adults.**—William R. Huggard declares that atelectasis, affecting a small portion of lung, is an extremely common condition at the apex but is overlooked owing to the ordinary method of examining the chest. The most frequent seats of this affection in the adult, according to the writer's observation, are from the apex to the second interspace in front; the suprascapular, and lastly the interscapular region. In order to detect the presence of this condition, percussion must be practised in front and behind before the patient begins to breathe deeply, and again at the end of the examination, when he has ventilated his lungs to the utmost. The limited form of atelectasis does not give rise to any symptoms apart from those due to the primary disease. It must be remembered that deep breathing which is called for during inspection often clears away or diminishes the evidence of atelectasis. The usual physical signs of atelectasis here referred to are dullness on percussion with feeble breath sounds, the dullness diminishing or passing off after a few deep breaths, the breath sounds at the same time becoming more distinct. Towards the end of the first two or three deep breaths, a few sticky or viscid râles can often be heard, but these grow gradually fainter and then disappear. As to treatment, the primary ailment must be attended to. In very early apical tuberculosis and in slight bronchial catarrh of growing young people, it is extremely common when percussion is employed both before and after the patient breathes deeply, to observe dullness over the apex of the lung at the first percussion, while a clear note will be heard after deep breathing. For the condition of atelectasis itself, systematic deep breathing must be employed—deep respirations for two minutes every hour. Exercises to develop the chest muscles should be taken when there are no contraindications. The patient must also avoid anything such as a cramped position, which might interfere with the free expansion of the chest.

**Colloid Carcinoma at Twelve Years of Age.**—James A. Milne observed this case. The patient was a boy 12 years old, who died after one day's illness. He first complained of abdominal pain. His temperature was 97 degrees F. His bowels acted, and he vomited once. Castor oil was administered, and by noon he had passed several motions which were simply loose, being neither offensive nor blood-stained. Later restlessness developed with slight low delirium. When the writer saw him next, about thirteen hours after the first symptom occurred, he was in collapse, the aspect being that of abdominal disease. Warmth, stimulants, and turpentine enemata were applied, and ergotin and morphine were administered. Marked tenesmus was present. The patient gradually sank and died that night. Necropsy disclosed a much-distended large intestine. The contents consisted of much gas and a dirty-brown fluid. In the upper part of the rectum was a hard mass which consisted of a concentric growth in the rectal wall extending for two inches along the rectum and constricting its cavity. There were several enlarged glands behind this mass. The intestinal wall was thickened, while the mucous membrane was eroded and ecchymotic. Both the growth and the glands were remarkably hard. Pathological examination demonstrated that the growth was a colloid carcinoma of the large intestine.

**Case of Poisoning from Sardines.**—Herbert Caiger reports this case. The patient was a girl seven years old. She ate freely of canned sardines which had a "funny" taste. Soon after headache developed and the child felt out of sorts the rest of the day. During the night she complained of pain in the abdomen. There was neither vomiting nor diarrhea. The next morning she still had stomach ache, but after drinking a little whiskey she went to sleep. A little after noon the patient was found to be in profound coma. The stomach was well washed out, but little was found in the washings but curds of milk. There was no special odor. Atropine sulphate was injected hypodermically. An enema was given but with little result. Later the stomach tube was passed and some castor oil was introduced into the stomach. Vomiting occurred and the bowels acted, but nevertheless the child died without recovering consciousness. At the post-mortem examination, the brain was found to be much congested, with numerous small petechial hemorrhages scattered over the surface as well as in its substance. Similar hemorrhages were seen beneath the pericardium. Nothing else of interest was noted. The child doubtless died from some poison generated in the canned sardines. The quantity of poisonous material probably increased in the alimentary canal after ingestion. There were doubtless microorganisms in the fish which multiplied and developed toxins in the stomach and bowels in the absence of vomiting and diarrhea. Enough of these poisons was absorbed to cause coma and death.

**Primary Syphilis of Conjunctiva.**—W. J. Forshaw had this patient under his care. She had been nursing a case of syphilis. Her eye which had been troubling her for about twenty-four hours, was painful; the conjunctiva was chemosed, projecting over the edge of the cornea, and there was slight discharge of watery fluid. A small gray patch was noted half-way between the limbus and fornix on the ocular conjunctiva. It was two mm. in size with a shreddy surface. It was not an ulcer but appeared like a slough. The entire ocular conjunctiva was engorged and swollen. The palpebral conjunctiva was not affected to any appreciable extent. The patch was the primary syphilitic sore. The eye was gently washed and fomentation often applied. There was not much change in the condition for ten days. At no time was there any ulcer, but the lesion gradually disappeared, leaving no mark on the conjunctiva. About the third week the preauricular cervical and submaxillary glands began to be painful, and they became enlarged and hard. The temperature rose every night, and the patient had pains and aches throughout the body. At the end of the sixth week, a well-marked rash appeared on the face, trunk, and limbs. There was no other sore besides the one on the eye. Infection was probably transmitted by the fingers, and carried up by movements of the lid. The affection was without doubt a primary syphilitic sore on the ocular conjunctiva.

**A New Treatment for "Housemaid's Knee."**—Buckley Pogson reports this case. The patient had a typical housemaid's knee. She was told to paint it with iodine. Four days later the knee was accidentally knocked against the banisters, with resulting complete disappearance of the swelling. A week later, locomotion was easy, painless, and apparently natural. The writer thinks that the "collision" treatment of an enlarged bursa patella is of sufficient interest to note.

*Berliner klinische Wochenschrift, October 9, 1905.*

**The Individual Dietetic Treatment of Gout.**—Carl von Noorden and Leopold Schliep describe a method of diet determination in gout which is intended to establish the tolerance of the arthritic patient for purin bodies in much the same way as it is customary to test the capacity of the diabetic for carbohydrates. The patient's excretion of endogenous uric acid when on a purin free diet is first determined. He is then given 400 grammes of beef on each

of two successive days, the uric acid determinations being continued. The healthy individual under such conditions promptly disposes of the nitrogenous material, and the excess of uric acid is completely excreted in at the most a day or two after the two beef days. The gouty patient, however, shows but little increase in uric acid excretion on the beef days themselves, and on the succeeding days the extra amount excreted is slight and never reaches the quantity it should. If, as is sometimes the case, the excretion is performed normally, it shows that the patient can manage this amount of beef and it may be added to his daily diet, but usually the test must be repeated one or more times with smaller amounts until the limit of toleration is reached. This quantity may then safely be allowed; though as the patient's capacity changes from time to time repetition of the test at intervals is necessary. The results obtained by this plan are considered more satisfactory by the authors than those following any other method of treatment.

**The Cure of an Epithelioma of the Skin by the Direct Rays of the Sun.**—Hirschberg describes the manner in which he unintentionally cured himself of an epithelioma of the ear. The lesion measured 1½ by ½ cm. and he had planned to have it removed by the knife on his return from a sojourn at Caux, situated near Lake Geneva at an altitude of 1100 meters. After two weeks here, during which the exceptionally fine weather permitted long walks in the sunshine, he noticed that the epithelioma had decreased in size, and suspecting the cause he then took pains to expose the ear to the light as much as possible. Two weeks later the entire ulcer had healed, leaving a smooth, healthy looking surface behind, and in the eight months that have elapsed since then no recurrence has appeared. The author urges further trials of this simple treatment, but says that it must be carried out in the mountains and preferably in winter, as the active ultra violet rays are nearly all absorbed by the dense, moist, dust-laden atmosphere of the lowlands, while in summer there is always the risk of causing dermatitis if the exposure to the sun be prolonged.

*Münchener medizinische Wochenschrift, October* 10, 1905.

**New Views on the Nature and Treatment of Chronic Constipation.**—Schmidt says that he believes that the prevailing view which attributes chronic constipation to a functional insufficiency of the motor apparatus of the intestine is not satisfactory, at least for a large number of cases. He is of the opinion that the symptoms in many instances, especially of the atonic form, are due to an abnormality of digestion by which the food is exhausted to an extreme degree and very little residue is left behind. In consequence the intestinal bacteria do not flourish as they should and the decomposition products which ordinarily stimulate the intestinal walls are not formed. In his attempts to add to the diet some harmless substance which should add bulk to the feces and prevent them from becoming so dry he finally hit upon agar agar. This is tasteless and unirritating, but when given dry mixed with the food in doses of 25 to 50 grammes it increases the bulk and moisture of the feces very notably. As it is not stimulating to the intestine in many cases it is advantageous to add to it a certain quantity of watery extract of cascara sagrada. Another combination from which good results have been obtained and whose use rests upon similar principles is one of liquid paraffin with cascara, and this is often a useful adjuvant to the agar agar compound. It is necessary, however, as these substances are not given as purgatives, to continue their use for long periods of time, and the usual treatment by massage, exercise, etc., is not to be neglected.

**Cyst Formation in the Remnants of the Appendix.**—Klemm describes three cases in which a partially destroyed appendix gave rise to the formation of retention cysts followed by abscesses. He explains the process by assuming that in consequence of swelling of the mucosa an occlusion is formed in the lumen of the appendix and dilatation of the distal part follows, owing to the inflammatory exudate. This may go on to the point of inducing necrosis at the site of the stenosis, so that the dilated portion becomes detached and receives its nutrition through the adhesions. When the internal tension becomes too great the sac ruptures and discharges its purulent contents intra or extraperitoneally. In one of the author's cases after drainage of an ordinary appendicular abscess without removal of the appendix, twelve times a pus collection formed under the old scar, and when permission was finally gained for a radical operation the cause was found to be a cyst of the distal stump of the appendix, detached from the cecum and fixed to the wall of the pelvis. Each time the sac had filled and ruptured the escaping pus had made its way to the surface along the track of the old scar tissue. The other cases illustrated the same condition in a similar but less marked manner.

**Can the Acarus of Scabies Transmit Leprosy?**—Bassewitz describes an instance of transmission of the leprosy bacillus which he considers proves that the itch mite can serve as intermediary. A patient with anesthetic leprosy was for some years kept in the general ward of the hospital of a small city in Brazil, without ever infecting any of the other patients. He finally was himself infected with scabies from another patient, and owing to his anesthetic condition the disease had progressed to an unusual degree before its nature was discovered; he was then isolated, on this account and not because of the leprosy. His attendant contracted the scabies, which promptly yielded to treatment, but two and a half years later he showed pronounced lesions of tubercular leprosy. The author concludes that every other source of infection can be excluded in this case, and suggests that the itch mite may be found to be the medium of transmission of the leprosy bacillus, which has hitherto been sought in vain in the fly, mosquito, and bedbug. It would therefore be of importance to examine the itch mites found on leprosy patients to determine whether they ever contain the Hansen bacillus, and also to regard patients having scabies in addition to leprosy as being especially likely to infect others. Mugliston has also observed a number of cases which go to prove the possibility of this mode of infection. A reference to his observations was made in the MEDICAL RECORD of August 26, 1905.

*Deutsche medizinische Wochenschrift, October* 5, 1905.

**The Etiology and Treatment of Appendicitis.**—Lucas Championnière, in discussing this subject, says that his experience leads him to believe that appendicitis is commoner now than formerly; in other words, that it is a modern disease. He has observed that at times the hospitals are filled with cases of appendicitis, and then again for long periods it seems to be rare, so that epidemic exacerbations of the morbidity may be observed. Furthermore, the disease is much commoner in some countries than in others, and it is seen with great frequency in regions that have lately been the seat of an epidemic of influenza. Again, influenza is sometimes very widespread in certain countries, such as Algeria, without being followed by a corresponding wave of appendicitis. In pursuing this inquiry further the author found that appendicitis was rare in monasteries, prisons, etc., where the diet was vegetarian, while on the contrary it is especially common in countries like England and the United States, where large quantities of meat are eaten. He therefore concludes that influenza in largely meat-fed people stands in a close etiological relationship to the disease, especially in individuals who are inclined to constipation, prophylaxis includes a restricted consumption of meat and a periodic artificial emptying of the gut. The author advocates operation as soon as the diagnosis is made, and he undertakes all cases, no matter how desperate they may seem. He prefers to make a direct incision over the rectus, pulling it to one side before incising the posterior sheath, and says that he does not see any post-operative hernias.

**The Bacteriological Diagnosis of Cholera.**—Friedberger and Luerssen have discovered that while the agglutination reaction for cholera organisms is perfectly satisfactory, as it is usually performed in laboratory experiments, it is open to a serious difficulty when it is to be applied in practical diagnostic work. This is on account of the observation that young cultures, when brought into contact with salt solution alone, show a pseudo agglutination which is quite as strong as that induced by active immune serum. Experiment showed that on reducing the concentration of the salt solution the tendency to pseudo agglutination became less; but if this dilute salt solution was used for making the bacterial emulsion from the agar growths the agglutinating power of the immune serum was interfered with. On further growth the organisms lose the property of inducing this pseudo agglutination, but it requires at least eleven, and often twelve to fifteen, hours for it to disappear so that there must be considerable delay in making the diagnosis if this method is to be relied on. The authors suggest that Pfeiffer's experiment be used for diagnostic purposes, by injecting into the peritoneal cavity of the experiment animals in the one case the culture alone, and in the other culture plus cholera rabbit serum, the difference in the appearance of the organisms being so great after even twenty minutes as to permit of a conclusion regarding the nature of the organisms. By using this method, instead of waiting for the cultures to reach a stage of development when pseudo agglutination is no longer to be feared, the diagnosis may be made from seven to ten hours earlier. The authors explain the non-detection of this pseudo agglutination before by the fact that the cultures used in laboratory work are nearly always growths that have been retransplanted several times since their isolation from the human body, and have, therefore, lost the power of pseudo agglutination even in young cultures.

**The Virus of Molluscum Contagiosum.**—Juliusberg, in order to test the ability of the contagiosum of this disease to pass through a porcelain filter, obtained a considerable quantity of the juice from the tumors, triturated it with sand, and diluted it with bouillon. He then passed it through a porcelain filter which both before and after proved itself impermeable to bacteria, and inoculated himself and two colleagues with the filtrate. In two cases there was no result, but after fifty days in one instance sixty mulluscа contagiosa developed and showed the typical molluscum bodies. It is therefore certain that the contagium of the disease is ultramicroscopic.

*American Journal of the Medical Sciences, September,* 1905.

**Hematemesis from Gastric Ulcer; Notes on Over 200 Cases.**—W. Gilman Thompson cites cases which illustrate his statement that it sometimes happens that diagnosis of the exact condition is most difficult as between hemorrhage from a circumscribed ulcer and in which operation may prove successful, and that from a mucosa generally congested and not amenable to surgical treatment. The so-called "cardinal symptoms" are also variable and inconstant. The writer declares that he is not yet prepared to accept a definite clinical classification of gastric ulcer into acute and chronic types based upon hematemesis, as attempted by various authorities. For it must be admitted that a single large hemorrhage may denote a chronic ulcer, equally with an acute one. The important difficulty lies in differentiating the cases of diffuse punctate hemorrhage. The estimation of the mortality of gastric ulcer by statistical methods is liable to misinterpretation. The mortality from cases of gastroenterostomy for gastric ulcer appears to be lessening gradually under improved technique. The great majority of hospital cases occur among young women who are seamstresses, domestic servants, factory operatives, and so on. The writer believes that cases in which a single large hemorrhage occurs and in which there have been antecedent symptoms, should be operated upon, as well as those suffering from a recurring hemorrhage. He adds also as indicating operative intervention those cases in which the patient's life is miserable through pain or in danger from persistent vomiting and emaciation, and in which medical treatment has failed.

**Examination of the Blood in Pulmonary Tuberculosis.**—Josephus T. Ullom and Frank A. Craig from their study of a series of cases, present the following conclusions. They declare, however, that the number of cases is too limited and the field covered too narrow, to afford deductions which could be considered final. In pulmonary tuberculosis without cavity formation a mild anemia, with a decrease in erythrocytes and a relatively greater decrease in hemoglobin, is constant. From the standpoint of prognosis an increase of the erythrocytes, in cases without cavity formation, is of favorable significance. In advanced cases a decrease of the leucocytes is of unfavorable import. In their investigations, the writers have received the impression that the actual increase of lymphocytes seems to correspond to the increase of resistance on the part of the organism to the tuberculous infection, but further study is required to confirm this deduction. The transitionals seem to follow the same rule as the lymphocytes in this regard. At the beginning of the investigation the eosinophiles seemed to increase with the patient's improvement, but further study did not support this view.

**Rest in the Treatment of Laryngeal and Pulmonary Tuberculosis.**—W. Peyre Porcher declares that next to violent paroxysms of cough and perhaps exceeding them, reckless and prolonged phonation does more toward destroying the laryngeal mucous membrane than any other factor. He strongly advocates entire rest of the larynx by total cessation of phonation. He adds that it is not alone in cases of laryngeal tuberculosis that complete rest of the larynx and pharynx is indicated, but he points out the advantages of this treatment in cases of ordinary pulmonary tuberculosis. It lessens the amount of cough and consequent prostration, hyperpyrexia, perspiration, and so on. Ankylosis of the joints does not follow absence of phonation even after a period of several months. There appears to be sufficient motion in ordinary respiration to prevent it. By complete rest the physiological power of the patient to resist the disease is increased. The writer believes that rest, either partial or complete, should be paramount in all cases.

**Concerning the Causes of Gallstones.**—Edwin Beer tersely sums up the results of his observations as follows: Naunyn's factors—stagnation of bile plus inflammation of the bile-passage mucosa—do not seem to be sufficient by themselves to lead to gallstone formation, even though the time allowed for the working of the causes be adequate. The writer's first series of cases shows that these two factors lead to stone formation in patients who previously had gallstones. In this series there is the first real evidence of the factors underlying gallstone production and the causes of cholelithiasis in human beings, the third factor being a faulty hepatic metabolism. When this exists, stones are formed. In its absence they are not produced, even though the first two factors are present.

**Xerostoma.**—Lewis S. Somers declares that as an independent affection *per se* the condition of xerostoma or dry mouth is exceedingly unusual. Although the various theories in regard to the etiology of the affection are most diverse, still they all appear to have an underlying basis of a nerve origin of the disease. Xerostoma is essentially an affection of middle age or later years. It is of exceptional occurrence in those under forty. It is seen most often in women, for with but few exceptions males do not seem to be affected. In not a few cases the general health remains unimpaired for a long period. The degree of xerostoma does not seem to bear any relation either to constitutional impairment or even to changes in digestion. Aside from the dryness of the buccal and adjacent mucous membranes, the tongue offers the most marked features. It is fissured to a greater or less extent and lacks its epithelial coating in part. Excessive dryness of the skin has been noted. Dental decay is quite constant. When xerostoma in a severe form has once become established, the condition remains practically as long as the patient lives. As to treatment, galvanism and pilocarpine have seemed to give the best temporary results in the greater number of cases. Aqueous or oily solutions containing various medicinal substances may be employed for the constant dryness of the mucosa of the upper respiratory tract.

**Clinical Investigations of the Digestion in the Insane.**—David Murray Cowie and Florence Allen Inch conclude that: In states of mental depression (melancholia) hyperacidity is the rule, occurring in 71.4 per cent. of von Noorden's fourteen cases, 81.8 per cent of the writers' twenty-two cases, or in 77.7 per cent. of all cases. Males and females are equally affected. This hyperacidity is due to a true hyperchlorhydria. Hypertotal acidity also occurred in the writers' cases, and in this respect they correspond exactly with those reported by von Noorden. The hyperchlorhydria is of moderate degree, is fairly constant, and is associated with increased peptic power and rapid evacuation. The increased secretion is due to the neurosis or psychosis and not to proliferative changes in the glands, as is evidenced by the presence of increased secretion associated with degenerative changes in the glandular elements, and of the entire mucosa. The evacuation of the stomach is usually normal or somewhat hastened after the Ewald test breakfast, while after the large stimulus of the Riegel meal and ordinary Asylum meal it is more often hastened. In the cases showing hyperchlorhydria the peptic value is never below normal and is often increased. Many of the insane suffer from various forms of gastrointestinal disease. These conditions are frequently overlooked. The writers urge the necessity of examining systematically in these cases the secretions and functions of the body, including the stomach contents. The signs of disease in the insane are almost entirely objective, and thus it is essential to make use of every modern method of value in diagnosing the disease. Cancer and gastric ulcer may often be recognized at the beginning. It is not improbable that the mental symptoms in these cases will proportionately decrease with proper treatment.

**The Relations Between Climate and Health.**—William S. Washburn, in his discussion of the Philippine Archipelago, presents the following conclusions: With respect to the principal climatological factors, temperature, humidity, and atmospheric movements, the climate of these islands is not extreme, as it is distinctly insular in character, the greater part of the land area being not far distant from the ocean. There are other modifying influences which obtain in parts of the archipelago, such as general oceanic and local interisland currents, prevailing winds, elevation, the state of cultivation, and drainage of the soil, and the presence of forests and other plant life. Excluding localities in the tropics characterized by excessive heat, high relative humidity, or unhealthful soil conditions, acclimation or physiological adaptation of the white man to tropical environment is possible. If acclimation is possible, colonization is possible. Failures of the white race to live in the tropics and maintain health, excluding localities indicated in the second conclusion, appear to have been due principally to nonobservance of the rules of personal, domestic, and public hygiene. As a rule, Americans appear to become acclimated in the Philippines during the third year of residence. With sanitary surroundings and by observing the rules of personal and domestic hygiene, residence of Americans in the Philippine Islands appears to be attended with as little danger of disease and death as residence in the United States under similar conditions.

# Book Reviews.

PATHOLOGY AND MORBID ANATOMY. By J. HENRY GREEN, M.D., F.R.C.P., Consulting Physician and Emeritus Lecturer on Clinical Medicine at Charing Cross Hospital, London, etc. Tenth American Revised from the Tenth English Edition. Revised and Enlarged by W. CECIL BOSANQUET, M.A., M.D. (Oxon.), F.R.C.P. (Lond.), Assistant Physician (Late Pathologist) to Charing Cross Hospital, London, etc. With a Colored Plate and 348 Illustrations in the Text. Philadelphia and New York: Lea Bros. & Co., 1905.

GREEN'S Pathology certainly needs no introduction to the American medical profession. Few among us have not pored over its pages, and few can not look back upon the hours thus spent as upon some of the most pleasant ones of our undergraduate reading. The book now comes forth in its tenth American edition, which has been revised from the corresponding English issue. On the whole the charms of the old book have been preserved—its clear, forceful style, its brevity, and its clean-cut definitions and descriptions. The advances of science have made additions and revisions innumerable necessary in each edition, and the present one has not been an exception. The work of the reviser has been chiefly concerned with the chapters on parasitology and immunity, and a new chapter dealing with autointoxications and nutritional diseases has been added. We regret that no mention is made of *Uncinaria americana*, (Stiles), and that in the chapter on the gonococcus nothing is said of the special culture media needed for its growth. The infectious theory of rheumatism has not been well developed; thus, on p. 528 we note "rheumatic poison" vaguely spoken of. But these are minor defects and are really not essential to the general object of the book, which is the education of students in the elements of pathology.

TRATADO DE GINECOLOGÍA. POR MIGUEL A. FARGAS, Catodratico de Obstetrica y Ginecologia de la Facultad de Medicina de Barcelona, etc. Tomo II. Fasciculo I. Enfermedades del Utero. Enfermedades de los Anexos. Barcelona: Salvat y Ca, S. en C., 1905.

THE present installment of the second volume of Professor Fargas' exhaustive treatise on gynecology deals with diseases of the uterus. The first volume, dealing with prolegomena and diseases of the external genitals and the vagina, was reviewed some time since in this column, and the praise accorded the work on that occasion holds good for the second installment of the book. The author has drawn freely from cosmopolitan literature and gives a very complete presentation of his subject, especially in the chapters on fibroid growths, cancer of the uterus, and uterine displacements. As in the first volume especial attention is given to operative technique, but precise directions are also to be found for palliative methods, including electrotherapy. Radiotherapy is not discussed, however, under the heading of cancer of the uterus.

THE FOOD INSPECTOR'S HANDBOOK. By FRANCIS VACHER, Medical Officer of Health for Cheshire, etc. Fourth Edition. Illustrated. London: Sanitary Publishing Co.; New York: D. Van Nostrand Co., 1905.

THE fourth edidtion of this small volume on Food Inspection has been carefully revised and brought up to date. The laws of the United Kingdom concerning food inspection are now fully covered in this book, through the addition of a supplementary chapter on the statutory powers of food inspectors. The work is an elementary handbook for those who desire to qualify themselves as inspectors of food, especially as inspectors of meat, and will be found valuable by persons preparing for civil service examinations for the post of sanitary inspector, inspector of nuisances, etc.

A SYSTEMATIC TREATISE ON MATERIA MEDICA AND THERAPEUTICS, with Reference to the Most Direct Action of Drugs. By FINLEY ELLINGWOOD, M.D., Professor of Materia Medica in Bennett Medical College, Chicago; late Professor of Chemistry in Bennett Medical College; Secretary of the National Eclectic Medical Association; Author of "A Synopsis of Medical Chemistry," "Manual of Urinalysis"; Editor of Chicago "Medical Times." With a Condensed Consideration of Pharmacy and Pharmacognosy by PROF. JOHN URI LLOYD, Ph.M., Ph.D., late President American Pharmaceutical Association, Professor of Chemistry and Pharmacy in the Eclectic Medical Institute of Cincinnati, Author of "Eudorlpha." Fifth Edition, thoroughly revised and greatly enlarged. Published by the Chicago Medical Times Publishing Co., 1905.

THIS volume presents the subjects of Materia Medica and Therapeutics from the standpoint of the Eclectic School. Hence the reader will expect to find the names of several drugs and preparations not at all familiar to him; at the same time he will note several new methods of treatment. The work is stimulating and crisply written, and the physician will obtain many new ideas from a perusal of its pages. It is a pity that the book was not prepared more carefully. On the title page this new edition is said to be the fifth, and also to be thoroughly revised; on the first page of the preface we are told that it is the sixth edition, and that the typographical errors found in a former edition are eliminated. Yet the book abounds in typographical and other errors, such as hystology (page 11), systitis (page 421), midriatic (page 225), fleuroscope (page 756), scorbutis (page 805), trychosis (page 630), ilocolitis (pages 643 and 703), ihocolitis and colitis (page 683), hyperiodrosis pedum (page 702). The Latin expressions fare no better; witness the following: Caffeine citratis effervescens (page 261), olium olivæ (page 387), ferrum bromide (page 119), liniment saponis (page 387), per orem (page 387), syrupus rhei et potassa compositis (page 380), tinctura Tolutani and syrupus Tolutani (page 301), aceps lima hydrosus (page 701). The chemical formulæ are equally unfortunate. Among others incorrectly given we note those for nitrogen monoxide, chloral, bromoform, potassium bichromate.

THE ERA KEY TO THE U. S. P. A Complete List of the Drugs and Preparations of the United States Pharmacopœia Eighth decennial revision. New York: The Pharmaceutical Era, 1905.

THE publishers announce a new edition of the well-known "Era Key to the U. S. P." whose object is to further the introduction and employment of the official drugs and preparations of the United States Pharmacopœia, the eighth revision of which is now in force. The book comes in vest pocket size and gives in sixty-three pages much important information required by the physician who desires to prescribe pharmaceutical remedies their official names, synonyms, and constituent parts, with average doses in both metric and English systems. The little book would have been more useful had there been added a list of the proprietary remedies recently admitted, with their pharmacopœial names. There is probably not one practitioner in five hundred who knows the official name of trional, for example; yet to be ethical he must prescribe it by the pharmacopœial name, and not the trade name.

A TEXT-BOOK OF THE PRACTICE OF MEDICINE. By James M. ANDERS, M.D., Ph.D., LL.D., Professor of Medicine and of Clinical Medicine at the Medico-Chirurgical College, Philadelphia. Seventh edition, revised and enlarged. Philadelphia and London: W. B. Saunders & Company, 1905.

IT was so recently that we noticed in this column the sixth edition of Dr. Anders' well-known and justly valued treatise that there is little more to be said regarding this new edition. The appearance of a new and revised edition of a book every year or two is an evidence of its popularity, and that it meets the needs of students and practitioners. The author lays special emphasis on the two most important branches of medical practice—diagnosis and treatment—and, unlike some of the other makers of text-books, he approaches the therapeutic sections with apparent confidence, as though the writing of them was of some utility, and not a mere concession to custom. Myasthenia gravis and the spotted fever of the Rockies are subjects introduced in this edition for the first time, as also are examination of patients for diagnosis of diseases of the stomach, splanchnoptosis, and Cammidge's test for glycerose in the urine. Certain other individual affections have been rewritten and additions have been made to tropical diseases. The book seems to be quite free from errors, though there are a few; for example, the author has labeled a picture of *Spirochæta obermeieri* "The bacillus of relapsing fever," as though unaware that the organism is now regarded as probably a protozoan parasite, and not a bacterium.

THE READY REFERENCE HAND-BOOK OF DISEASES OF THE SKIN. By GEORGE THOMAS JACKSON, M.D., Chief of Clinic and Instructor in Dermatology, College of Physicians and Surgeons (Columbia University), New York. Fifth edition, enlarged and thoroughly revised. With 91 engravings and 3 colored plates. Philadelphia and New York: Lea Brothers & Company, 1905.

THE features that have always characterized this book are the alphabetical arrangement, lucidity of statement, and the special attention devoted to symptomatology, diagnosis, and treatment. The present edition is larger than its predecessors, and contains sections on Acne agminata, Acne necrotisans et exulcerans serpiginosa nasi, Acne telangiectodes, Acrodermatitis perstans, Acrodermatitis chronica atrophicans, Asteatosis, Botryomycosis hominis, Cheilitis exfoliativa, Erythema serpens Congenital ichtyosiform erythrodermia, Folliclis, Depilating folliculitis of the limbs, Granuloma annulare, Granulosis rubra nasi, Hyponomoderma, Koilonychia, Multiple benign sarcoid, and Veld sore. To students and practitioners who want a handy yet thoroughly reliable work on dermatology we can commend the present volume.

## NEW YORK STATE MEDICAL ASSOCIATION.

*Twenty-second Annual Meeting, Held in New York City, October 16, 17, 18, and 19, 1905.*

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. J. RIDDLE GOFFE, IN THE CHAIR.

(*Continued from page 679.*)

FOURTH DAY—THURSDAY, OCTOBER 19.

**Spontaneous Cure in Cancer; Its Significance in Relation to the Ultimate Solution of the Problem of the Cure of Cancer.**—DR. HARVEY R. GAYLORD, of Buffalo, N. Y., spoke of the occasional occurrence of spontaneous cure of cancer occurring in mice in the laboratories in various parts of the country, and said that in the Buffalo laboratory they had inoculated 1500 mice and had noted seventy true, unquestionable spontaneous cures, to which might be added twenty or thirty doubtful ones. They had now come to look upon spontaneous cure in cancer-inoculated mice as more or less of a constant occurrence, and the facts associated with this were of extreme importance. One of his assistants, Dr. Clews, had recently gotten together certain facts, and he found that in no case a mouse that had spontaneously recovered could be successfully inoculated; it endowed the animal with a permanent immunity. A number of undoubted spontaneous recoveries had occurred in the human being, which he referred to, especially mentioning the case of Senger. This was a case of epithelioma of the cheek, opposite a carious tooth. Operation was recommended. There was much swelling in the submaxillary region and of the submental glands. The tooth was withdrawn, and in three months the tumor had entirely disappeared. Another patient presented himself with a similar condition of affairs. He operated upon a tumor the size of a cherry. There was the same submaxillary enlargement. The tooth was withdrawn. The sections of the epithelioma proved its nature without doubt. In the course of a few weeks the patient returned and the rest of the tumor had entirely disappeared. In going through the literature the best cases were found in the most malignant forms of cancer, the choroidal; there were eight cases of undoubted spontaneous cures of this most malignant type. He detailed a case that had already been published in Munich which represented the features of all the cases. Certain points bearing upon spontaneous cures were told. Experiments had shown, for instance, that without any doubt mice that had recovered spontaneously from cancer were positively immune. It had been shown that there was a period in these cancers in mice in which the tumor can be made to retrograde with ease. If there was much hemorrhage and this blood got between the epithelial cells of the tumor, there followed an atrophy of the cells. It seemed that contact with the blood in the early stages took away the power of these cells of proliferation. Squeezing the tumor and causing hemorrhage into it produced the same effect. Again it was interesting that if the tumor had attained a certain size, the same procedure would cause it to grow rapidly. The injection, too, of adrenalin into the tumor caused it to grow rapidly. The histological portion of the tumor retrograding had a similar appearance as one retrograding under the action of the *x*-ray. In one experiment one-half the mice were bled, causing the tumor to develop rapidly; the other half were not bled, and the tumor retrograded. The determining factor was whether the tumor did well after being interfered with, and this was a question of how much residual immunity there was. A great field for experimentation was now open in determining to what extent hemorrhages influenced the tumors. Loss of blood at operations might be advantageous, while prolonged anesthesia might be disadvantageous. The highest percentage of spontaneous cures occurred during the earlier stages of the growth. A good many mice had a natural immunity, and they could not be successfully inoculated. He said that it was quite obvious that in dealing with mice they were dealing with quite different material than was to be found at the bedside. At the bedside one usually encountered the fatal cases. At the present time certain positive deductions had been made regarding the immunity factor, and he hoped that some practical use would soon result. Early operation and treatment was most important. The only new thing was the experimental deductions of this factor of immunity.

DR. J. RIDDLE GOFFE referred to the hopeful view expressed of this most terrible disease.

DR. WILLIAM B. COLEY said that in a large proportion of cases of cancer of the lip in which the glands had not been removed, finally resulted in permanent cure, and he believed this was in line with Dr. Gaylord's thought. This occurred more frequently than people believed. The real cure for cancer was early operation; but in the not distant future means of attacking the disease would be presented which would give far more hopeful results and a far larger proportion of cures than at the present time.

DR. C. C. FREDERICK of Buffalo reported a case of spontaneous cure of cancer of the uterus occurring in a woman, 40 years old, the mother of several children, and who had been bleeding for two and a half years. When he saw her the room was foul and a foul smelling mass was noted in the vagina. The temperature was from 101° to 102° most of the time. Recently she had had a profuse hemorrhage and the pulse was very rapid and, taking all in all, she looked as though her chances of life were very slim. The diagnosis of the case was undoubted, the tumor involving the cervix, infiltrating the vaginal walls in its neighborhood. He advised building the patient up, and, when in better condition, operating in order to prolong life for a few months. Months passed away, when he was informed by a neighbor that she was well; that two or three weeks after he had seen her she passed a large, stinking mass, and had improved so since that she was now well and weighed 160 pounds. He examined her, and all he could find was a cicatrix. The cervix was entirely gone. There was a small opening into the uterus, all that remained of that organ. The pathologist's report was that it was a carcinoma. This was a case in which Christian Science got the credit of curing her, she embracing this faith after he first saw her.

DR. MARY E. DUNNING of Newburgh said that five years ago she saw a woman, aged 60 years, who was very anemic and who had a mass extending midway to the umbilicus, inguinal glands very much enlarged, and a profuse discharge from the vagina. A diagnosis of carcinoma was made and a hopeless prognosis given. Another physician was called in and made the same diagnosis. Six months or a year later Dr. Dunning was informed that the patient was cured. Two years later she appeared at her office again and the vaginal examination showed nothing except an atrophied uterus. The abdominal examination showed a slight mass to the right side that she thought might be a misplaced or enlarged kidney. Later fecal vomiting set in and operation for intestinal obstruction revealed a perfectly normal atrophied uterus. But there was a mass at the lower lobe of the liver carcinomatous in character which caused complete obstruction of the bowels.

DR. CHARLES P. NOBLE of Philadelphia reported a case of deciduoma malignum operated upon five years ago, the special point of interest being the length of time between the pregnancy and the malignant growth. At the time of operation apparently the wall of the bladder was invaded by the growth. Her condition was bad. It was clear that to remove the entire growth meant a resection of one-half the bladder; owing to the patient's bad condition, he did not feel warranted in doing a total hysterectomy, and so did a supravaginal amputation. Some months after the operation one could distinctly feel a mass in the bladder wall where the malignant growth was left. One year after operation examination showed that there was no longer any abnormality about the bladder. The patient's health remained good for four years, when she was attacked with pneumonia and pleurisy. It was the opinion of the family

physician that there was a recurrence in the lung. The patient lived one year after this attack. The chest was carefully examined, but no consolidation of the lung was made out. There was no question about the spontaneous disappearance of the cancer in the pelvis. Personally he believed that that patient died from heart trouble, but free from cancer.

**The Therapy of Carcinoma.**—Dr. Samuel Lloyd of New York presented this communication. He made two statements, first, that in the first stage of cancer was merely a local disease, but later it became constitutional, and, second, that it was capable of transmission from one individual to another of the same species. He said that the first proposition was accepted by most, if not all, clinicians. The happiest results were obtained with those small epitheliomata about the face and lips. If they were recognized early and removed they seldom recurred. The results became much more unsatisfactory if the deeper structures were included. When cancer had become constitutional the possibility of its cure had passed from certainty to almost impossibility. Since Dr. Willy Meyer and Dr. Wm. S. Halstead advised the radical operation for the removal of cancer of the breast, statistics showed that instead of 25 per cent. of cures the number of cures had risen to from 42 to 45 per cent. It was evident that much more would be obtained when the general profession shook off their lethargy in regard to carcinoma and urged their patients to prompt and radical treatment so soon as they became conscious of the presence of the disease in any case. It was a disgrace for a physician to allow a cancer to pass to the inoperable stage without doing everything in his power to get the patient into the hands of an experienced surgeon. Heidhaim was convinced by his investigations that we were still ignorant of the extension of cancer in its own neighborhood, but he believed that the "path and the way in which cancer spread were quite different according to the kind of cancer, its anatomical structure, and the function of the diseased organ or tissue." Dr. Lloyd said that the question as to whether cancer was communicable would still be considered debatable by many, but he was absolutely convinced of this fact himself and had been collecting data for some years which went to prove this statement. Most convincing was the increasing ratio of cancer to the population, as shown by the health statistics of different countries. It was also shown that cancer was more common in thickly populated districts. In the poorer sections of Paris there were from 137 to 145 deaths per 100,000, while in the richer and cleaner sections there were but 75 deaths per 100,000. The same thing had been found to be true in other cities. This was also true of country regions. He had had several personal experiences where the disease had no doubt been communicated from one individual to another. One man, an engineer, had cancer of the tongue, from which he died, and about a year later the night engineer working in the same place presented himself with cancer of the anterior pillar of the fauces. They had used the same drinking cup for several years. A man died of cancer of the stomach, and within two years Lloyd operated upon the wife for cancer of the breast; he had also operated upon a case of cancer of the stomach in a man whose brother had died of cancer a few months previously. A woman died of cancer of the breast, and two years later he operated upon her sister, who had nursed her, for cancer of the stomach. There was no previous cancer in the family. A physician's wife was operated upon for cancer of the stomach, the physician himself developed cancer in the lower jaw. Autoinfection with cancer was now a well established fact. Gueillot believed that the epithelial origin of cancer would soon be admitted. Orth said, "Every cancer must be designated as an epithelioma." "The epithelial cells form the essential element of the cancer—they are not only the most important, but indeed the only important element." It was well known that we are constantly shedding our epithelial cells. If the normal were shed, so were the abnormal, and they might become a veritable cancer graft. In order to control the spread of cancer it became essential to prevent the dissemination of whatever element communicated the disease. The public should be educated to consider it contagious. Dressings removed from cancer cases should be immediately incinerated. The patient should be advised to avoid direct contact with others, kissing, etc. When a discharging wound was present, it should be covered with impervious dressing. In the second place, it should be remembered that cancer was engrafted upon points of ulceration, chronic irritation or developed in regions where abnormal epithelial tissue already existed. All contact with cancerous ulcers, and the common use of beds, utensils, drinking vessels, linen, etc., with cancerous patients should be avoided. All inflammatory lesions should be treated and cured, and all abnormal collections of epithelial cells should be removed. As to the *x*-ray, he said that it produced a form of obliterative endarteritis, and the curative effect was produced by cutting off the blood supply of the involved area. If the results of the treatment were always positive, if they were prompt in their effects and could be confined to the diseased area alone, and if they caused an equal amount of change in the superficial and the deep tissues, without endangering the life of the patient, we might feel that the advocates of this treatment were correct. The treatment of cancer by this method sometimes caused an increase in the rapidity of the growth of the malignant tissue. Several cases were cited to prove this statement. That the constant use of the *x*-ray was not prophylactic was shown by the fact that cancer developed in the *x*-ray burns on the hands of those constantly using this method of treatment. Radium offered some advantages over the *x*-ray in that it could be applied directly within the mass and its range of action might be directed to the deeper structures. He still believed that some superficial cancers could best be treated by some one of the caustics, especially those away from the mucocutaneous borders and involving only the superficial layers of the skin. No application of a paste or caustic should be made to a cancer that had penetrated beyond this. In some of these cases it might be possible to apply the actual cautery and get rid of all the diseased tissue. The advertising of cancer cures without operation was a dangerous practice. In case one did employ a paste, Jenning's or Bougard's was probably the best. The former was composed of hydrochlorate of cocaine, 2 parts; caustic potash, 12 parts; vaselin, 6 parts. The formula of the latter was, wheat flour, 60 grammes; starch, 60 grammes; arsenic, 1 gramme; cinnabar, 5 grammes; sal ammoniac, 5 grammes; corrosive sublimate, 0.50 centigrammes; solution of chloride of zinc at 52° F, 245 grammes. For the superficial cutaneous epitheliomata of the face terchlorid of antimony had proven superior to any of the pastes in the reader's hands. Treatment with toxins, antitoxins, or sera had thus far failed. From the standpoint of clinical observation as well as in consequence of statistical results he thought that we were forced to the conclusion that up to the present time that early and complete excision of all cancerous disease was the best known method of treatment, and it was important to urge on the profession the necessity of immediate operation as soon as the malignant change in any given case was recognized. This ought not to deter from further investigations along other lines. He also urged constant watchfulness for several years after operation.

Dr. William B. Coley agreed with practically all that Dr. Lloyd had stated, particularly regarding the communicability of cancer, which he had believed for many years, and he related some cases showing the communicability of carcinoma. In his lectures to nurses he emphasized his belief in the communicability of cancer. This same feeling regarding tuberculosis once existed. Cases of autoinfection were numerous, and surgeons now treated cancer wounds with care, believing that the knife could carry the disease to other parts. With regard to the non-surgical treatment of cancer, the *x*-ray was now commanding attention, and he called attention to the fact that many cases reported two, three, or four years ago, since lost sight of, were still being

reported as cures. But now the three year limit had gone by, and reports of these cases would be anxiously awaited. His own experience dealt with 170 cases of malignant disease treated with the *x*-ray, none of these being operable cases. Of 40 cases of cancer of the breast, there was only one in which the cancer disappeared under the influence of the *x*-ray. It promptly recurred in the other cases. What he said regarding carcinoma applied equally as well to sarcoma. At Harvard, among 130 cases there was not a single case of deep-seated cancer cured by the *x*-ray. The same report came from the Middlesex Hospital, England, and from Mikulicz clinic as well. He referred to the report of Dr. Collins, at the recent meeting of the American Medical Association, that 94 per cent. of the cases of tumor of the breast in persons between the ages of 20 and 30 were not malignant. With regard to the use of the *x*-ray as a pre-operative method there were objections; while attempting this the disease might extend and metastasis occur. He said he was strongly opposed to this pre-operative treatment with the *x*-ray.

**Mediastinal Tumors.**—Dr. William Francis Campbell of Brooklyn read this paper. In April, 1905, there was referred to him for operation a farmer, 21 years old, with a diagnosis of goiter. There was loss of voice, a swelling just above sternal notch, embarrassment of respiration, and difficult deglutition. A study of these symptoms elicited from the patient was exceedingly interesting, but the point of interest was the sequence of the symptoms. The very first symptom was loss of voice, which led him to doubt the previous diagnosis, for in goiter loss of voice was a late symptom, not an early one; in goiter the appearance of the tumor was first and loss of voice secondary; here the loss of voice was first and the appearance of the tumor secondary. On the second night after entering the hospital the patient was sitting as usual by the open window. This was his most comfortable method of resting. He arose to get something, after walking several steps fell and expired. Autopsy showed a tumor of the mediastinum involving the pericardium and extending into the sac. It extended backward and upward into the neck and was about the size of the head of a seven months' fetus. The pathologist reported it to be a limphosarcoma.

**The Sanatorium for Tuberculosis Patients and Its Medical and Social Mission.**—Dr. S. A. Knopf of New York read this paper. He said that by the admission of a patient to a sanatorium, a frequently dangerous center of infection was made inoffensive and the patient was given the greatest possible chance of cure. If in the advanced stage he was made as comfortable as lay in the power of human skill with all the modern therapeutic means at command. The sanatorium taught that phthisiobia was as unjust as it was cruel. It showed that the careful and conscientious consumptive was as safe an individual to associate with as anybody else and that the sanatoria for consumptives were not a danger to the neighborhood. It cured the consumptive, whenever his case was curable and demonstrated the curability of the disease independently of climate. It made the patient a hygienic factor when he returned to his former environment and demonstrated the preventability of tuberculous diseases. The patient would have been taught the love of fresh air by day and night, to shun vitiated atmosphere and the air of the saloon and the crowded meeting places. He would have learned the value of simple, pure and good food and how much more advantageous it was for him and his children to spend his money for food than for intoxicating liquors. The sanatoria for children, some of which reported as many as 75 per cent. of cures, prevented many a strongly predisposed child from ever becoming consumptive in later years or going through life crippled and deformed. In summarizing the social mission of the sanatorium for tuberculous patients, he said we beheld an even greater destiny. The sanatorium taught true democracy, compassion and benevolence to the aristocratic, the rich and the indifferent. It taught the fallacy of a belief in alcohol as a food or specific for tuberculosis and thus combated alcoholism. It taught the disorderly to become orderly and offered to the uneducated an opportunity for education. It taught love for pure, fresh air, personal and general cleanliness, and thus, indirectly prevented not only tuberculosis, but many other diseases whose origin must be traced to lack of fresh air, to filth, and to unsanitary habitation and habits. The young medical man entering the sanatorium as assistant, was given an opportunity to become a trained diagnostician of incipient tuberculosis, and thus he would be most helpful in the solution of the tuberculosis problem. The sanatorium showed the benefit of housing the laborer in a model tenement, of paying him reasonable wages, and of having him work in a sanitary place. It showed that it did not pay to overwork the adult and that it was criminal to employ children. Thus, the sanatorium, through its medical and social mission, not only diminished tuberculosis among the masses but made their lot a happier one, furthered charity, humanity, and liberty. It had been asked what would become of the numerous sanatorium buildings when tuberculosis would have so decreased as to no longer fill them. He said that by reason of their location and construction the sanatoria for adults would make admirable homes for the aged and infirm who now crowded our almshouses and the seaside sanatoria would give to the children and overworked mothers of our crowded cities much needed vacation homes. Hence we should continue to build sanatoria where they were needed.

(*To be continued.*)

## MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

*Fifty-fifth Annual Meeting, Held at Scranton, September 26, 27, and 28, 1905.*

(Special Report to the Medical Record.)

(*Continued from page 681.*)

SECTION "B."

FIRST DAY—TUESDAY, SEPTEMBER 26.

Dr. Erasmus V. Swing, Coatesville, First Vice-President, in the Chair.

**The Address in Surgery.**—Dr. Jonathan M. Wainwright, Scranton, took for his subject, "The Value of Spinal Analgesia in Shock." The author referred particularly to the danger from shock following amputations for crushed lower extremities and gave in detail, illustrated by charts, the blood pressure of dogs in which experiments had been performed, (1) under ether, and (2) under spinal analgesia produced by cocaine. The blood pressure invariably decreased where the analgesia was not employed, while in those cases in which it was employed, it either arose or remained stationary. In two clinical cases he had also been able to demonstrate these results, which he viewed as showing the great value of the method in those cases where there was grave danger from shock.

**The Results of Surgical Treatment in Exophthalmic Goiter.**—Dr. B. Farquhar Curtis, New York, stated that out of seven cases he had operated on by means of sympathectomy two died from acute thyroidism, one relapsed nine months after the operation and died from the original disease with acute endocarditis, and only one was completely cured five years after the operation. He stated that he preferred the operation of thyroidectomy, as it could be easier done under a local anesthetic, the mortality was not so high, and the scars did not come so far up in the neck He reported three cases of operation by this method.

**Focal Diagnosis of Operable Tumors of the Cerebrum.**—Dr. Charles K. Mills, Philadelphia, referred to the advance in localization and removal of tumors in this region during the two last decades, citing as notable causes of failure in these cases, particularly in the past, difficulties and imperfections in localization, the small size of the openings for removal, and relative imperfections of surgical technique. He illustrated, by means of charts, the division of the cerebellum into prefrontal, motor, auditory,

midfrontal, parietal, and occipital areas. He stated that the tumor was more apt to develop in the region controlling the upper extremities than the lower, and urged that the incision made be from three to four inches in length.

**Surgery in Relation to Operable Lesions of the Cerebrum.**—Dr. CHARLES H. FRAZIER, Philadelphia, stated that one of the main causes of failure in these cases was the fact that they came too late; and particularly is this true of Jacksonian epilepsy. Trephining of any kind was liable to produce adhesions, and he did not favor the placing of silver foil between the dura and the skull; he cited a case in which it had produced convulsions, which after the removal of the silver foil ceased. Indiscriminate exploratory craniectomy was not advised, but in cases of infantile encephalitis, if the lesion could not be localized, he felt it to be justifiable. He reported two cases, in one of which the brain was exposed and a cortical clot removed within about a month, and the patient made an almost complete recovery. In conclusion, he stated that early diagnosis was more frequent, the percentage of cases in which the tumor was found was larger, and the mortality not so high as formerly, which he attributed largely to better methods of diagnosis and larger openings, and in many instances palliative operations are justifiable.

**An Instrument Affording a Quick and Safe Method of Entering the Skull with the Minimum Destruction of Bone and Always Preserving a Vital Flap.**—By Dr. H. C. MASLAND, Philadelphia. The instrument was on the circular saw pattern, the depth of the incision being adjustable by the operator, and the propelling power was electricity. It also had an adjustable inner guard if desired.

**Treatment of Trifacial Neuralgia by Complete Avulsion of the Peripheral Branches of the Trigeminal Nerve.**—Dr. ERNEST LAPLACE, Philadelphia, stated that he believed the recurrence in many of these cases after excision of the inferior dental nerve was due to regeneration, illustrating this by the regeneration of nerve growths in other parts of the body. He called attention to the fact that whenever the nerve was twisted or squeezed tightly it would break, and stated that in order that the nerve might be extracted as far as possible, he had used a specially curved hemostatic forceps, and by twisting the nerve very slowly, taking as much as a minute or two minutes for a single twist, he was able to extract it almost entire; the whole operation requiring from twelve to twenty minutes.

Dr. JOHN B. ROBERTS, Philadelphia, commented particularly on the value of the operation outlined by Dr. Laplace, and also the diagnostic importance of the work of Dr. Mills.

**The Essentials of Successful Röntgen Therapy.**—Dr. CHARLES LESTER LEONARD, Philadelphia, called attention to the fact that the *x*-rays might act as a stimulant, alterative, analgesic, or escharotic; too light a dose would stimulate malignant tissue, while a too strong dose was liable to destroy the other parts; the best results could be secured only by careful adaptation to each individual patient. One difficulty was that sometimes the effect was not manifested for several days, which caused danger of cumulative action.

**The Adjustment of Radiation for Various Physiological Effects.**—Dr. RUSSELL H. BOGGS, Pittsburg, called attention to the fact that before successful application of this agent could be brought about careful study of the physiological action and application to the individual cases were required. He dwelt particularly upon the degree of vacuum, and stated that during the last two years he had treated various cases by five different degrees, the cases being classified under the following groups: (1) Acne and unulcerated lesions; (2) epithelioma and lupus; (3) cancer of the uterus, tuberculous glands, etc; (4) sarcoma.

**The Treatment of Mediastinal Carcinoma by the X-ray.**—Dr. G. E. PFAHLER, Philadelphia, reported six cases of carcinoma of the mediastinum following carcinoma of the breast, the first occurring in a woman aged thirty-six, who had a primary growth removed; sixteen months later a secondary growth appeared, which was removed, and she was able to do her ordinary work. The second case was a secondary growth appearing three years after the removal of the primary lesion, which was treated on several occasions for a period varying from six weeks to three months with the *x*-ray; the patient had now apparently recovered. The third, fourth, and fifth cases were in women, aged respectively sixty-two, fifty-two, and sixty-two years, in whom the treatment had produced good palliative results.

Dr. JAY F. SCHAMBERG, Philadelphia, stated that in deep-seated malignant disease there was no doubt that surgical intervention should be imposed in the operable cases, but he urged the use of the *x*-rays as an adjunct thereto, or as a palliative measure in inoperable conditions.

Dr. JOHN C. PRICE, Scranton, emphasized the importance of careful individual regulation of the strength and quality of the rays, and particularly deprecated the fact that they were too often employed by the general practitioners, without sufficient regard to these points.

Dr. ERNEST LAPLACE, Philadelphia, said that during the early stages, if the cancer cell was of low grade, this agent would exert a beneficial effect or possibly destroy the growth. He referred to the work of Doyen of Paris, which he had had an opportunity of observing a couple of weeks ago, and reported a series of experiments conducted upon guinea pigs by that author; all but twenty-one of the animals had died of the disease, and seven of the latter showed neoplastic cells, which, however, were not far enough advanced to cause fatal results.

Dr. CHARLES P. NOBLE, Philadelphia, stated that the diagnosis in the case reported by Dr. Pfahler had been confirmed by clinical and microscopical observation, and felt that the field for this agent was rather in postoperative work or in inoperable cases.

SECOND DAY—WEDNESDAY, SEPTEMBER 27.

**Conservative Treatment of the Enlarged Prostate.**—Dr. H. M. CHRISTIAN, Philadelphia, stated that the patient when first seen by the surgeon would present one of the two conditions: (1) Good general health, moderate enlargement of the gland, with increased urethral length, partial retention, residual urine, varying from three to six ounces, urine sterile or slightly cloudy, indicating slight infection of the bladder; catheter used without difficulty once or twice daily; or (2) general health fair, marked enlargement and increased urethral length, complete retention, absolute catheter life, chronic cystitis, and the introduction of the catheter difficult and painful. He did not view prostatectomy, either suprapubic or perineal, as a minor operation, and, while recommending it for the second class, felt that its use should be limited to those cases in which there was acute or chronic cystitis, painful or difficult insertion of the catheter, or when the occupation of the patient prevented the use of this instrument.

**Recent Results in Cancer Research which Bear on the Parasitic Theory.**—Dr. H. R. GAYLORD, Buffalo, reviewed fully the literature regarding the transplantation of tumors, with a view to proving that they had their origin in germs. Among the various operations he referred to one reported by Ehrlich, in which the tumor, started by inoculation from a carcinomatous growth, had, at the thirteenth generation, developed into a sarcoma. He said that spontaneous recovery had taken place in about fifty per cent. of the cases inoculated, and stated that the literature showed fourteen cases to have recovered. He also referred to experiments made by injecting the serum from immune mice, or by mixing the blood of immune mice with the germ as prepared for inoculating others, which would prevent its taking any effect. He gave a detailed account of the experiments conducted under his observation, particularly with a view to proving the germ theory.

Dr. WILLIAM L. RODMAN, Philadelphia, congratulated the author on the work that he had done, but felt that it was incumbent on the advocates of the germ theory of the origin of cancer to bring more evidence to bear on the point.

He remarked the fact that changes in the mode of life seemed to increase the susceptibility to this disease, the same as it did to tuberculosis, citing as instance in both diseases the Africans and American Indians. As a contradiction of the germ theory he referred to the fact that there was no reported case of a physician becoming infected while doing an operation.

Dr. J. C. Bateson, Scranton, referred to observations he had made some years ago with a view to ascertaining the causative agent in cancer, particularly in regard to heredity, and urged, in view of the rapid increase of this disease, the necessity for careful study.

Dr. Ernest Laplace, Philadelphia, stated that he believed there were two things necessary to the development of cancer, a proper seed and a fertile soil.

Dr. Gaylord, in closing, remarked that, while there was very little difference in the facts as found by the various observers in their experimental work on cancer, they had drawn far different conclusions therefrom. He called particular attention to the fact that cancer cells increased in virulence with each successive generation, and believed that many more investigations and experiments would have to be made before the treatment of cancer by immune serum would become of practical value.

**Three Patients with Meningocele Who Recovered.**—Dr. George W Guthrie, Wilkes-Barre, in this paper discussed three varieties of the disease, meningocele, meningomyolocele (meningoencephalocele, when the growth contains brain matter, as well as membranes), and syringomyelocele, and the etiology and prognosis. He stated that the most favorable cases for operation were embraced under the first head, and reported three cases, one of which was cured spontaneously and the other two by operation.

**Additional Observations Upon the Treatment of Empyema with Special Reference to Irrigation of the Pleural Cavities.**—Dr. P. Y. Eisenberg, Norristown, said that the puncture method was gradually giving place to more radical measures, simple incision, resection of one or more ribs, and finally decortication when resection failed. He reviewed particularly the literature of reported deaths due to flushing of the empyemic cavity, and believed that causes of death could probably be explained by the physical condition of the patient, the use of too much force, too sudden distension of the pleural cavity, etc., rather than the flushing *per se*. The irrigating fluid should either be sterile water, weak boric acid solution (three per cent.) or salt solution. He stated that he had employed this method in six cases during the last two years with invariably good results.

**Fractures of the Head of the Radius.**—Dr. T. Turner Thomas, Philadelphia, stated that a search of the literature on this subject revealed only forty-eight reported cases, six of which were diagnosed during life; but he had been able to secure from four skiagraphers in Philadelphia records of about fifty-five cases. He expressed the belief that the cases were more frequent than was supposed, and mentioned, as important diagnostic factors, interference with rotation and supination, localized pain, and tenderness, together with a history of falling on the hand. He recommended immobilization for three or four weeks, after which passive movements should be begun gently. Several pathological specimens and *x*-ray pictures were also exhibited.

**The Address in Obstetrics.**—Dr. Ella B. Everitt, Philadelphia, took for her subject "What Constitutes Operability in Cancer of the Uterus," and stated that the best results would be accomplished in three ways: (1) Bringing about conditions favorable to earlier diagnosis; (2) improvement in operative technique; (3) clear and widespread knowledge of when to apply radical measures, and when to be content with palliative relief. Among the factors requiring consideration under the latter heading were (*a*) the proportion of the uterus involved; (*b*) the extension beyond the uterus; (*c*) the operative measures available. After reviewing the various operations for this condition and their development, she stated that the question of prime importance should always be what is best for this individual patient, believing that operative interference was justifiable only when a radical cure, or at least a prolongation of life under more favorable circumstances, could be fairly expected.

**Ectopic Gestation.**—Dr. Charles P. Noble, Philadelphia, stated that during the past sixteen years he had operated upon ninety-one cases, eighty-nine by abdominal section and four by the vaginal route, two of the latter subsequently requiring abdominal section. In forty-four of these cases the pregnancy was in the left tube; in forty in the right; in seven the report did not show which. In his experience the causes were usually mechanical. Early diagnosis and prompt operative interference were urged as important factors, and it was believed that careful consideration of the history would greatly facilitate the diagnosis.

Dr. George D. Nutt, Williamsport, believed that the condition was much more frequent than was supposed before abdominal surgery came into prominence, in most cases, in his experience, being due to mechanical factors. He reported a case in which a rupture of the right tube containing a quantity of blood had been completely walled off from the abdominal cavity, and the menstrual periods had been regular for seven months prior to the operation.

Dr. Richard H. Gibbons, New York, urged the necessity for early diagnosis and prompt operation, and reported several cases, including one of rupture of the broad ligament which he had operated on several years ago, with complete success.

Dr. J. C. O'Day, Oil City, mentioned, as strong diagnostic symptoms, long-standing history of sterility without apparent cause, with sudden cessation of the menstrual periods and pelvic pain. Among the causative factors were mentioned gonorrhea, torsion of the tubes, and other mechanical factors, and he reported a case in which an operation for a cystic ovary revealed a ruptured extrauterine pregnancy in the left tube, occurring quite a time before and completely walled off.

**The Restitution to Normal after Childbirth.**—Dr. Barton Cooke Hirst, Philadelphia, stated that injuries of the genital canal and backward displacement of the uterus constituted more than one-third of over six thousand cases of diseases of women that had come under his observation; and if to this number were added the puerperal infections, pelvic inflammations, etc., after childbirth, and abortion, subinvolution, endometritis, and other pathological consequences of parturition, they would constitute far the larger proportion, and among the remainder would be a limited number of neoplasms, genital tuberculosis, and gonorrhea. The patient should be carefully watched during the period of gestation and parturition, and sufficient examinations made afterwards, to insure the physician that all the organs have returned to normal.

**Uterine Curettage.**—Dr. E. E. Montgomery, Philadelphia, stated that the indications for the use of the curette were chronic endometritis, polypoid or mucous growths projecting from the mucous surface of the uterine cavity, retrodisplacements, if followed by measures to restore the normal position, pelvic inflammation, if associated with measures to correct the intraperitoneal disorders, carcinoma for the purpose of securing scrapings for study, and the retention of products of embryonic life. The contradictions were acute endometritis, intrauterine myomata, or any other cases in the absence of intrauterine inflammation. Aseptic precautions should be observed in the preparation of operator, patient, and instruments—Pratt's dilators and metal bougies were recommended—and the operation should be performed only by one skilled in the work, and drainage must be established.

**Significance and Management of Chronic Uterine Hemorrhage.**—Dr. George Erety Shoemaker, Philadelphia, said that the determination of whether or not the flow was normal could be made only by comparison with the other

periods of the same individual during a time she was in a healthy condition, and cited, among the causes for hemorrhage, passive congestion of the pelvic vessels, pelvic disease outside of the uterus, prolapsed and cystic ovaries, chronic adherent inflammatory disease, disorders of pregnancy, partial placenta previa, threatened abortion, and extrauterine pregnancy. He deprecated the idea that preceding the menopause there was likely to be slight hemorrhage and urged careful examination and prompt treatment of these, as well as all other cases.

Dr. Richard H. Gibbons, New York, reported a case in which after he had curetted and employed a bichloride solution of one to three thousand, he opened the abdominal cavity to complete the operation and found the intestines blistered, which could only be explained by the escape of fluid into the abdominal cavity. In this case, after the removal of the appendix and one tube and shortening of the round ligament, the woman made a good recovery.

**The Technique Employed in the Last One Hundred Laparotomies.**—Dr. L. J. Hammond, Philadelphia, discussed at length the literature on the subject and cited the opinions of different operators, both for and against the use of drainage. He reported one hundred cases, thirty-six with localized pus and sixty-four in which pus was absent, consisting of appendicitis, cholelithiasis, etc., with but four fatalities, in one of which drainage had been used. He expressed the opinion that drainage should be employed only when there was some positive indication for it; in cases of disease of the gall-bladder, however, drainage should always be employed.

Dr. J. G. Clarke, Philadelphia, referred to a series of one thousand cases which he had worked out several years ago, and stated that as the number of operations became greater, the number of times which drainage was employed decreased, and he believed that it should be the exception rather than the rule.

Dr. J. Montgomery Baldy, Philadelphia, believed the less the abdominal contents were handled the better, and that the more experienced the operator became the less he would employ drainage.

**The Management of Pus Cases in Abdominal Surgery.**—Dr. Reed Burns, Scranton, stated that in empyema of the gall-bladder the best results followed cholecystectomy, and that in cases of pyosalpinx, suppurating ovaries and tubes, ovarian abscesses, suppurating cysts, and acute salpingitis operation was the method of choice. In appendical abscess he recommended that the pus be evacuated before opening up the abdomen. He reported a number of cases of peritoneal abscess, perforation of the appendix, and one of rupture of the gall-bladder.

Dr. W. L. Estes, South Bethlehem, felt that the reason drainage did not produce the results expected in many cases was due to the improper method of employment, and stated that in some cases an important factor, particularly with women, was the raising of the head of the bed.

Dr. J. C. O'Day, Oil City, said the gall-bladder should be left in and drained wherever possible, owing to the danger of fibrous degeneration and closure of the common duct.

Dr. William L. Rodman, Philadelphia, did not favor the flushing of the abdominal cavity when the pus was confined to a limited and circumscribed area, and said that, while cholecystectomy had its field, it should be confined to cases of gangrene or other disease of the gall bladder.

Dr. Richard H. Gibbons, New York, urged the necessity for immediate operation in all cases of appendicitis, and believed that that organ should be taken out whenever a laparotomy was done. In regard to the gall-bladder he felt it had better be left in, unless malignant degeneration was present.

Dr. J. E. O'Brien, Scranton, said the greatest need was of a competent surgeon. He remarked that during the last eight years Dr. Burns had operated on one hundred and twelve cases of appendicitis, with but two deaths.

Dr. Charles P. Noble, Philadelphia, said that drainage should be employed only when especially indicated; but he believed that it was better to remove the source of the infection and then pack with sterile gauze than to flush out the abdomen in cases of free pus and general peritonitis.

*(To be continued.)*

## MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

*Thirty-first Annual Meeting, held at Indianapolis, Indiana, October 10, 11, and 12, 1905.*

The President, Dr. Bransford Lewis of St. Louis, in the Chair.

Addresses of welcome were delivered by Mayor John W. Holtzmann, on behalf of the city of Indianapolis, and by Dr. W. N. Wishard, on behalf of the local profession, which were responded to by Dr. H. O. Walker of Detroit.

The scientific work was divided into two sections, medical and surgical.

### SURGICAL SECTION.

**Surgical Dressing.**—Dr. Carl E. Black, of Jacksonville, Ill., presented a preliminary report on the technique of the after-dressing of surgical cases. He pointed out briefly the principal elements necessary for the proper dressing of a wound, whether it were a surgical or an accidental wound. While the technique differed somewhat in different kinds of wounds, the fundamental principles were the same in all. Such a consideration divided itself into (1) the patient; certain modifications must always be made to suit the individual case. (2) Those things which were auxiliary to the dressing itself, but which did not come in contact with the wound. (3) The surgeon or nurse making the dressing and his or her assistant. (4) The instruments, dressings, and solutions coming in contact with the wound. Septic wounds should be so dressed that there was no opportunity for a further mixture of infection in the wound, nor any opportunity for the infectious material from the wound in any way to be scattered where it could come in contact with other wounds. These two points should always be the basic principles of a surgical dressing, and should always be kept prominently in mind by those undertaking the dressing of wounds. To facilitate dressings and to economize in materials, and at the same time carry out a thorough technique, the author had arranged and had been using for some time a plan which had proved quite satisfactory. He had devised a box which contained everything that might come in contact with the wound, and everything, excepting the instruments, could be purchased in ordinary stores of towns and were not expensive.

Dr. John Young Brown of St. Louis, Mo., thought the secret of the success of the essayist in dressing wounds was due largely to the thorough system he had inaugurated. System was everything in surgery, as in business.

Dr. O. H. Elbrecht of St. Louis, Mo., said the sooner surgeons reached a standard in the sizes of dressings, in tapes, squares, oblongs, etc., the less confusion there would be on the part of the surgeon in going from one hospital to another to do surgical work. He mentioned the plan adopted by him in the hospital with which he was connected.

Dr. C. E. Ruth of Keokuk, Ia., said that the sooner the profession came to a realization of the needs pointed out by the essayist, the less confusion there would be, as well as lessening very materially the liability to infection.

Dr. Miles F. Porter of Fort Wayne, Ind., said the keynote of success in the management of surgical cases was system and simplicity. One should attempt to do away with the necessity of dressing wounds until they were healed in all cases where this was possible. The essayist spoke of there being no necessity for dressing an antiseptic wound until the stitches had been removed. The speaker said there should be no stitches to remove in the ordinary aseptic wound, no matter where it was located, and in the

ordinary treatment of septic cases there was a great deal more dressing than was called for. The dressing of a wound after it was made should be looked upon as an evil to be avoided as far as possible.

Dr. Black, in closing, said that the gist of the whole matter was system for the purpose of saving time, of safety for the patient, and of economy.

**Curettage in Septic Cases.**—Dr. C. E. Ruth of Keokuk, Ia., stated that prevention must always be the most important treatment and must always include hygienic asepsis of the patient and physician and great care in examination. No instrumentation in any variety of puerperal sepsis should be considered which denuded the uterine mucosa and opened up tissues not in any sense protected from septic infection, the utmost gentleness being used to avoid any possibility of puncturing the softened or disintegrated uterine wall. The curette should never be used in such cases, certainly not a small or sharp one, and then only in the least serious of these cases, namely, saprophytic intoxication, which was not sepsis. He had for many years been satisfied with a placental detacher of his own device, which answered every purpose with a minimum danger of perforation. Streptococcic and staphylococcic were the most serious of puerperal infections, as these, on the manifestation of symptoms, passed beyond all possible reach of removal by any form of curettage. While curettage could do no good, it might do much harm in disseminating infection and in causing uterine perforation. Within the last two and a half years the author had operated upon four cases of puerperal sepsis which illustrated the dangers of curettage. These cases were reported in detail.

Dr. O. H. Elbrecht of St. Louis, Mo., thought that many deaths were due to the curette being used in cases of septic uteri. It was just as criminal, in his judgment, to introduce a curette into a septic or infected uterus as it was a sound or curette for the purpose of producing criminal abortion. He mentioned one case in which a physician curetted a uterus contrary to his advice, and the next day the patient died. He mentioned two other cases of sapremia that terminated fatally, as he believed, from curettage of the uterus.

Dr. H. O. Walker of Detroit said the paper was timely, and one could not condemn too strongly the indiscriminate use of intrauterine curettes and irrigators. Many deaths were undoubtedly due to the indiscriminate use of these instruments.

Dr. John Young Brown said that while the indiscriminate use of the curette was dangerous, the instrument nevertheless had an important function to fulfill. Where there were decomposing membranes or fragments of retained placenta, the uterus should be cleaned out.

Dr. Hannah M. Graham of Indianapolis related her experience in treating the class of cases under discussion. She used an applicator, and not a sharp or dull curette. Cotton was wrapped around the applicator, which was saturated with carbolic acid, and the debris left in the uterus was swabbed out. It was her practice, too, to use a fenestrated catheter as a drainage tube, through which peroxide of hydrogen was injected every two to three hours, by either herself or the nurse, and she had had good success by this method.

Dr. A. M. Hayden of Evansville, Ind., concurred in the remarks of Dr. Brown. When a physician was called to see a patient whose uterus contained a broken-down fetus or fragments of placenta, if he failed to clean out that uterus the speaker thought he was criminally negligent. Patients went on for weeks with elevation of temperature due to sepsis, and would not get well without the judicious use of the curette, while if the uterus was cleaned out the patients would recover in a short time. He advocated the use of placental forceps for removing débris or pieces of retained placenta without disturbing or breaking down nature's protection.

Dr. Thomas B. Noble of Indianapolis uttered a word in defense of the uterine curette, saying it was an instrument for prevention as well as cure. The proper way was to interpret the pathology that one had to contend with, remembering that the curette was a means to an end. If a woman was suffering from high temperature, rapid pulse, prostration, due to saprophytic material in the uterus, which could be removed by mechanical means, the physician did her an injustice if he left the uterus alone, simply trusting to the *vis medicatrix naturæ* to take care of it.

Dr. G. Frank Lydston of Chicago said he did not believe that the essayist or those who spoke so emphatically in condemnation of the curette, would fail, as a matter of practice, to differentiate between the post-abortive septic phenomena and the post-puerperal septic phenomena. He did not believe that any of the speakers intended to convey the idea that the curette was to be condemned and never to be used. If one were called to see a woman who had been suffering from general sapremia for several weeks, who was in such a condition that it was evident dissolution was not far away if something was not done, if the history was such that material had been left behind in the uterus, and she was having a temperature of 106°, he would certainly not treat such a woman surgically or provide drainage by way of the vagina through the medium of vaginal irrigation, but would remove the septic material from the uterus. If this were not done the case was doomed, and many women in such a condition recovered under proper intrauterine treatment.

Dr. A. H. Ferguson of Chicago mentioned a case that terminated fatally on account of meddlesome interference on the part of a physician.

Dr. Ruth, in closing, said he thought a good deal of the discussion arose from a misunderstanding or failure to differentiate between the varieties of infection that one had to deal with. There was no danger from a careful curettage in a case of putrescent uterus in which there was not added to the intoxication or sapremia a septicemia.

**Artificial Hyperemia in Surgery.**—Dr. Alexander C. Wiener of Chicago pointed out the indications for this treatment in surgery, as follows: (1) Subacute mild inflammations of joints and soft tissues were relieved rapidly. (2) Acute purulent inflammations of soft tissues either on the extremities or the head. (3) Acute and subacute inflammations of joints and purulent arthritis; gonorrheal infection of joints. In these cases the elastic bandage had to be applied in such a manner as to produce energetic venous stasis, without causing pain to the sufferer. In acute inflammations comparatively light constriction produced an immense hyperemia. This conclusively showed that the arterial blood was not diminished but slackened. Cases were cited in which excellent results were obtained by the Bier method.

**Surgery of the Gall-Bladder and Its Ducts.**—Dr. H. O. Walker of Detroit, Mich., related his experience with 185 cases upon which he operated. He quoted from a former paper written by him years ago, saying that what he said then still obtained to-day. (1) Jaundice, which heretofore had been regarded as almost pathognomonic of the presence of gallstones, was present in only about 20 per cent. of gallstone cases. (2) Pain in the region of the gall-bladder did not by any means indicate the presence of gallstones, but was quite as often the result of a kinking of the systic duct from lesions, the result of one or more attacks of cholecystitis combined with pericholecystitis. (3) The passage of stones in the feces was not as common as was formerly supposed, for colics were rarely successful in passing a stone from the gall-bladder. (4) Empyema of the gall-bladder was not always felt by palpation, for frequent attacks of cholecystitis tended to diminish the size of the gall-bladder. (5) Tumors of the gall-bladder without pain or jaundice indicated a simple dropsy, while a painful, distended gall-bladder indicated empyema, and when accompanied by jaundice indicated constriction of the choledochus. (6) A hard nodular painful tumor of the gall-bladder, with or without jaundice, was almost certain evidence of carcinoma. (7) Obstruction of the choledochus, accompanied with inflamma-

tion and jaundice, quickly disappeared after the passage of the stones into the papilla of the duodenum. Cholelithiasis was of greater frequency than was supposed. Approximately every tenth individual had concretions in the gall-bladder, yet only about one in twenty ever complained of their presence, so that quiet stones needed no treatment. It was only the cholecystitis and cholangitis which made manifest the irritable presence of gallstones without demanding treatment, namely, medicinal and surgical. The conditions that required operative intervention were (1) an acute seropurulent cholecystitis with accompanying pericholecystitis. (2) Persistent and frequent pains due to adhesions between the gall-bladder, intestines, stomach, and omentum. (3) Chronic obstruction of the common duct. (4) Chronic empyema of the gall-bladder and its accompanying accidents. Cholecystectomy was undoubtedly advisable where the gall-bladder had been subject to frequent attacks of inflammation, and where chronic septic conditions existed. The author reported an interesting case in which he removed the gall-bladder and fixed the right kidney.

**Retroperitoneal Teratoma.**—Dr. C. M. Nicholson of St. Louis, Mo., read a paper on this subject. The tumor described was a teratoma of the abdominal cavity, remarkable not only because of its rare occurrence, rapid growth, and total absence of symptoms until three weeks before death, but because with its substance had been found a chorion epithelioma. At the post-mortem examination made by Dr. S. S. Stahl, a fibrous capsule was found, enclosing a semi-solid mass and adherent only in the median line and to the right kidney. Not without much difficulty could the tumor be removed, so intimately was it attached to the structure anterior to the vertebral column. The abdominal aorta from the first dorsal vertebra to the fourth lumbar was closely attached to the growth. The tumor weighed a little less than two pounds. It was right-angled and lobulated, the lobules being smooth and extending in different directions. On cutting, the tumor was soft, the anterior inferior extremity being partially cystic. Some of the cysts were as large as a hazelnut. The remainder of the growth appeared solid. The outer surface of the tumor was covered with a distinct fibrous capsule. Paraffin section of the Zenker-fixed tissue showed a very complicated mass. Portions of organs were found corresponding in embryonic origin to all the general layers. Skin, cutaneous organs, central nervous system, peripheral nerves, represented the epiblast. Mucous glands, tubes, cysts with epithelial lining, were indicative of the hypoblast. Bone, cartilage, fibrous tissue, constituted the mesoblastic structures.

Dr Joseph Riley Eastman of Indianapolis said he had had a remarkable experience in relation to tumors of this character. He had had two cases of complete precoccygeal teratomata, but he had not had such a case as the one related by Dr. Nicholson. His two cases were simply instances of precoccygeal teratomata. They were not cases of inclusio fetalis which Dr. Nicholson had reported. He related a case in which his father had removed almost a complete skeleton from the [illegible] of a man in middle age.

Dr Nicholson, in closing, stated that cancroid epithelioma occurring in a case of teratoma was extremely rare, and so far as a search of the literature was concerned, he had been unable to find a similar instance. Examination of the tumor in question had clearly the presence of [illegible] germ layers.

**Some of the Fallacies in the Clinical Diagnosis of Gonorrhea.**—Dr. G. Frank Lydston of Chicago discussed some of the more dangerous of the fallacies in the diagnosis of gonorrhea, with especial reference to prognosis as regards the infectiousness of a given individual to other and healthy persons with whom he or she might come in sexual contact. He considered, first, the possibility of excluding infectiousness in the case of a woman under suspicion, or who was known to have had gonorrhea. That the most dangerous type of infection of the female was that in which the external manifestations of the disease were absent, or wanting, was coming to be well understood by both gynecological and genitourinary specialists. The explanation of the relatively great danger of infection of others by such subjects was not so thoroughly understood as it should be. Gonorrheal urethritis in the female, when it had assumed the chronic form, might present no secretion whatever upon external examination. There might be little or no vaginal, cervical, or uterine discharge, and even such as there was might upon examination fail to disclose the microorganisms of gonorrhea. A swab or probe passed into the urethra might return perfectly clean. Notwithstanding this apparent lack of infection in the urethra, the mucous glands might be involved, and under the influence of sexual excitement and the mechanical effect of coitus the physiological hypersecretion might convey gonococci in abundance to the meatus. The result was sufficiently obvious. The author presented clinical facts which would seem to make it impossible for a physician to state in any given case that a woman was free from infection. This was one of the strongest arguments against regulation and medical inspection of prostitutes. He entertained serious objections to the medical profession constituting itself an assurance society for the protection of the social evil, but aside from this scruple, there remained the fact that no reliable system of inspection or examination could be devised. The speaker was firmly convinced that in many cases of infection of healthy women by a latent gonorrhea of the husband, mixed infection was responsible, and the resulting pathological condition in the female was non-specific. Its being non-specific, however, did not preclude the possibility of its becoming very serious.

Dr. W. E. Washburn of Kewanee, Ill., exhibited an improved urethrotome.

**Irritation of the Bladder.**—Dr. A. Ravogli of Cincinnati, O., said that in many abnormal conditions of the genitourinary organs and also of the urine itself this affection came on as a symptom in the form of the necessity of frequent micturition. This symptom could be produced by a number of intravesical and extravesical affections. In this condition the urination was so increased that it seemed the bladder could not tolerate the presence of urine. In some cases it occurred in the daytime only, in other cases at night, and in severe cases often in the day as well as in the night. The intervals between urination might be two hours, but in some cases the patient urinated every quarter of an hour, or even every five minutes. The patient would lose sleep, waste away, and was scarcely able to attend to his occupation. In reference to the causes, the urine might be the cause of irritation on account of its quantity or its quality. It might be too concentrated, contain urates, phosphates, sugar, etc., which maintained or kept up irritation of the bladder. The bladder itself might be the cause on account of an hyperæmic condition. This hyperæmia might be the result of vesical or of extravesical troubles. Phimosis, urethritis, prostatitis, neoplasms, perityphlitis, vulvitis, colpohyperplasia, etc. In other cases it was a pure neurosis, the consequence of epilepsy, hysteria, and eclampsia. Since the urethroscope and the cystoscope had been used, cases of irritation of the bladder without pathological condition had greatly diminished, and in many of them there had been found to be granulations or hyperæmia of the mucous membrane. There were two kinds of irritation of the bladder, one which was a local neurosis, and another which resulted from pathological alterations of the bladder or of the urethra. The affection was a stubborn one, but the detection of the causes would help greatly in the selection of appropriate treatment.

**Prostatectomy.**—Dr. W. D. Haines of Cincinnati, O., said that two patients, aged respectively 42 and 50 years, with small indurated prostate with obstruction, did well after perineal section and the removal of the gland, in that the catheter was abandoned and a troublesome cystitis relieved. One of the men suffered incontinence for a period of three

months after the operation, and the cure was incomplete as residual urine was found in both cases, and this despite easy bladder access by the sound or catheter. The author condemned the use of metallic instruments in prostatics for diagnostic purposes, or for the relief of urinary retention, as the danger of perforation and infection far outweigh the meager information or temporary relief thus obtained. One could confidently hope for complete cure in 30 per cent. of the cases submitted to prostatectomy, namely, release from catheter bondage, relief from bladder complications and restoration of urinary functions. In his experience with perineal prostatectomy seven cases had been functionally cured, nine showed residual urine, some of whom had had attacks of cystitis and dribbling, and five of these were suffering from incontinence six months to one year and a half after operation. Two cases required secondary operation, one for stone, and one for perineal fistula, making a total of sixteen cases, with ages ranging from 42 to 79 years, without mortality. While these results were far from ideal, the unfavorable physical condition present in the majority of them would in a measure militate against criticism as to the final outcome of this series.

**The Operative Treatment of Tuberculous Joints.**—Dr. Horace J. Whitacre of Cincinnati, Ohio, advocated four kinds of operations for tuberculous joint disease: First, osteotomy for the removal of an epiphyseal focus; second, erasion or arthrectomy of those cases, particularly in the young, where the focus was circumscribed and a fair amount of synovial membrane remained; third, excision; fourth, amputation. Osteotomy for the removal of a focus localized in the epiphyseal end of a bone was a most logical operation. Six cases of rather extensive tuberculosis of the knee were treated by arthrectomy or erasion. In four of these cases a complete cure of the disease with a useful stiff joint and good position was attained. In three of the cases a slight amount of motion giving some assistance to the patient in locomotion was regained. In two cases amputation was subsequently resorted to. These subsequent amputations occurred in patients who passed from his observation very soon after operation. They undoubtedly represented recurrence in a spot where the dissection had not been sufficiently thorough. Excision for a tuberculous joint had been reserved in his practice for those cases in which the bone ends were damaged.

**President's Address.**—Dr. Bransford Lewis, in his address, considered two subjects: (1) Some unrecognized responsibilities of press and State in conserving health, and (2) the prophylaxis of the so-called venereal diseases. He called attention to quack medical advertising in newspapers and magazines, and said that news managers provided against discrimination frequently by making unworthy advertisements resemble as closely as possible the regular news material of the paper, or by setting it up as telegraphic matter. He thought the press was *particeps criminis* in presenting such fraudulent material. There was a widely disseminated and growing belief that matters pertaining to sexual physiology and pathology should be taught in a simple way to the budding youth of both sexes in the course of their regular education, in order to place them in a position to resist the temptations that beset young life, by the clearer understanding that such instruction would afford. He would make use of educational channels of all sorts to spread the information desired in a scientific, dignified, truthful, and wholesome manner, and such instruction would be received in the spirit in which it was imparted. It was primarily to the education of the people to which we must look for providing either the required legislation or the belated impulse for self-respect and decency on the part of the newspapers in eliminating quack advertisements. Another subject which he considered well worthy of attention was the determination of practical methods of protecting the people from the far-reaching and disastrous effects of those diseases generally termed venereal, but which were not uncommonly entirely innocent in their development. He referred to gonorrhea, syphilis, and chancroid. These diseases prevailed to an extent undreamed of by the people and those in control of the public health of our country. He believed nothing was to be accomplished by prolonging a discussion as to the propriety of legal control and regulation of prostitution. Instead of trying to do what was impossible, to corral and disinfect all prostitutes, he would teach the public the dangers of prostitution, the dangers of the diseases to which it led, the prevalence of such diseases in daily life, and how they were acquired innocently, how they were to be avoided, and the necessity of seeking relief from them as soon as possible when they were acquired. The campaign of education must be the chief reliance, and the medical profession, followed by the ministry, instructors in institutions of learning in general, philanthropists, and leaders in public work, would have to be counted on as the imparters of such education.

(*To be continued.*)

## MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

*Stated Meeting, October 9, 1905.*

The President, Dr. Thomas E. Satterthwaite, in the Chair.

**Foods and Nutrition.**—Prof. R. H. Chittenden of Yale University read the introductory paper on this subject. He stated that there could be no exaggeration in emphasizing the importance of the daily diet in the maintenance of health, and in the establishment of a proper and normal condition of nutrition, and the numerous and varied fads of the present day in matters of diet all testified to the still unsettled condition of the public mind on that important subject. The physiologist and the practising physician likewise showed a noticeable lack of agreement as to what constituted a proper diet under normal conditions of life, to say nothing of the requirements in cases of disease. The physiological relationship between certain forms of diet and specific conditions of disease were obvious and easily illustrated; for example, no one needed to be told of the connection between carbohydrate feeding and the production of sugar, as in diabetes. Less readily discernible, however, and of more or less uncertain significance, were the secondary results of intemperance in diet, the effects of an excess of this or that article of food, and the equally important effects of a deficiency in some one or more dietary substance. Who could tell, with any degree of precision, the exact effects of an excess of proteid food upon the functions of the liver and the kidneys, or the effect of an accumulation of waste nitrogenous products upon the nervous system, or of different types and admixtures of foods upon the growth of the young? Yet these were all questions that called for definite answers, and with a full and complete knowledge of the laws of nutrition the answers might be forthcoming. Dr. Chittenden said that, in his judgment, two at least of the dread diseases of mankind, viz., cancer and tuberculosis, were probably the result of a disturbance of nutrition, in which at least the predisposing causes were to be found in excess of nutritive material in general in the blood, or to a disturbance in the balance of nutritive materials in the circulating medium, or, possibly, in the tissues themselves. The speaker said there was nothing original in this statement, although he had formed his opinion through independent reasoning and observation. In tuberculosis, while all recognized the importance of fresh air, there was still great uncertainty as to the character and extent of the diet best adapted for combating that disease; there was surely a reaction going on against the altogether too prevalent fashion of overfeeding. The speaker said that while we still had to admit a lack of definite knowledge as to what constituted a proper nutrition of the body, his own obser-

vations in that direction led him to believe that there was much of value to be learned in a study of the minimal quantities of food required to maintain health and strength; the real needs of the body for food were unquestionably very much below the amounts ordinarily consumed, and that being true, one might well ask the question, Did not that excess of food, for which the body had no true physiological need, in the long run imperil the health of the individual, diminish the ordinary powers of resistance, and so pave the way for various forms of disordered nutrition which we spoke of as disease?

**A Theory of Protein Metabolism.**—Otto Folin, Ph.D., of Waverley, Mass., read this paper. He said it was a well-known fact that the destruction of protein within the human body was diminished, but did not altogether cease when the supply of food protein was cut off. The greatest diminution in the daily protein destruction was obtained by the use of diets which contained liberal amounts of carbohydrates and fats, and which, at the same time, were free, or almost free, from nitrogenous constituents. Under the exclusive use of such nearly protein free diets the daily urinary nitrogen continued to diminish for from five to seven days, and then remained practically stationary at from 2.5 to 4 grains. The larger or more muscular the person, the more nitrogen did he eliminate toward the end of such a feeding experiment. Only urines rich in nitrogen had the chemical composition that was supposed to be normal. Every decided diminution in the total nitrogen was accompanied by unmistakable changes in the relative proportions of the more important nitrogenous products. The fall in total nitrogen was chiefly represented by a fall in the urea elimination. The prevailing idea that the urea contained about ninety per cent. of the total nitrogen in normal human urine was therefore erroneous. Urea nitrogen, representing ninety per cent. of the total, was found only when a great deal of protein was destroyed within the body, and when the urine in consequence was rich in total nitrogen. When the daily protein consumption was reduced, and the total nitrogen elimination was diminished, the per cent. of that nitrogen present as urea sank more and more, until it finally represented less than sixty, sometimes even less than fifty, per cent. of the total nitrogen. That fact had to be taken into account in the examination of pathological urines. When such urines were low in total nitrogen, the urea determination alone was very misleading. The urines might be normal, and yet might contain only five grams of nitrogen and only seven grams of urea. Since the urea nitrogen sank more rapidly than the total nitrogen when the daily protein catabolism was diminished, it followed that some other nitrogenous products must at the same time become relatively more and more prominent. The most interesting product in that connection was one that had received comparatively little attention in the urine analysis of the past, namely, creatinin. This was a simple compound containing about thirty-seven per cent. of nitrogen, and was present, the speaker believed, in all urines. As creatin it constituted the chief nitrogenous extractive in the extract of muscles. The occurrence of creatin and the absence of urea in muscles had always seemed a most peculiar circumstance in view of the fact that urea had been supposed to constitute the chief nitrogenous end product in protein catabolism. When the total daily catabolism was reduced, creatinin not only became more and more prominent as a catabolism product, but the absolute amount of creatinin eliminated was not at all affected by the diminution in the elimination of total nitrogen. The constancy in the creatinin elimination, and the constant presence of creatin in muscle extracts, when considered in connection with the enormous fluctuations in the urea elimination and the almost complete absence of urea or of any adequate precursor of urea in muscle extracts, seemed to indicate that those two products were the representatives of two different kinds of protein metabolism. Since the catabolism which gave rise to creatinin appeared to be for each individual a constant quantity, no matter how much or how little nitrogenous food was taken, and since its chief decomposition product was demonstrably always present in muscles and other tissues, it seemed justifiable to consider that metabolism as the tissue metabolism. On the other hand, since the catabolic processes which produced nearly all the urea varied within such enormous limits, and so directly with the supply of food protein, and since the urea was always strikingly absent in the muscles, it seemed fair to consider these catabolic processes as a part of a more localized and more specialized form of protein metabolism. To this form the speaker had given the name exogenous metabolism. The tissue metabolism represented the daily wear and tear of all the cells in all the different tissues, while the exogenous metabolism represented the specialized activities of certain definite organs, such as the digestive tract and the liver. The total quantity of tissue catabolism occurring in twenty-four hours depended only on the number and condition of the cells in the individual. The total quantity of the exogenous metabolism was independent of the size of the person; it depended normally only on the amount of available protein contained in the food.

**Distinctive Features of Animal and Vegetable Dietaries.**—Prof. La Fayette B. Mendal of Yale University read this paper. He stated that until very recent years the advocacy of unique dietary régimes, such as were involved in vegetarianism, or the preponderating use of animal foods, had been based upon considerations scarcely to be termed physiological. There was no little divergence of opinion, even among orthodox writers on diet, with respect to the proportion of animal foods which should be admitted into the daily diet. Inasmuch as even the vegetarians readily permitted the use of the eggs and milk of animals, the question at issue was essentially concerned with the physiological value of meat and its products. The speaker thought it would be readily admitted that man *could* nourish himself on an exclusive vegetarian régime, and the discussion was thus restricted to the relative advantages of the different systems. The ready digestibility of the meat proteids and the consequent availability of flesh products had always been contrasted with that of the proteids in plant materials, and it was undoubtedly true that a considerable larger proportion of the vegetable proteids was lost to the organism in the ordinary forms of vegetable diet. Vegetable proteids, *per se*, were as a rule not less digestible than those from animal sources, and the poorer utilization ordinarily recorded was attributable to the form in which the nutrients were present; in other words, to the peculiar texture of the crude material. The physician of to-day should be in a position to accept at correct value certain familar fallacies which were still widely current with respect to food products. One class of these fallacies rested upon the untenable assumption that the chemical composition of a foodstuff was an adequate index to its nutritive value; that might be essentially misleading when either proteids or fats or carbohydrates were exhibited in a form which the digestive apparatus could not satisfactorily appropriate. The essential improvements which the modern innovations in the form of prepared cereal foods had introduced related to their cooking and their palatability. That was particularly true of the oat products. The extravagant claims on the packages were no guarantee of extraordinary food value, although the product might be wholesome and nutritious; and the "malted," or so-called "predigested," preparations, as a rule, possessed no advantages beyond those obtained by thorough cooking. Well baked white bread was utilized even better than most of the ready to-eat preparations. The deficiency of the ordinary vegetable dietaries in proteids had long been the subject of criticism by the opponents of the vegetarian regimen. Impartially, that might more properly be spoken of as a paucity rather than a real deficiency of proteids, if we accepted the evidence afforded by the researches of Profssor Chittenden and of Dr. Folin on the actual proteid needs of the body.

Furthermore, it was well to bear in mind the recent progress in the production of palatable plant products which were decidedly rich in proteids, and were at present available in considerable variety and attractive form. That applied in particular to nuts and nut foods, some of which approached meat in composition. With extract of beef imitated by "yeast extracts," and likewise containing purin bases, and with nut meats competing with flesh products, it had to be admitted that the qualitative disinctions between animal and vegetable dietaries were becoming far less marked than they were in former years. Vegetarianism undoubtedly had its place in ameliorating various functional disorders, and that without laying claim to any mysterious properties. In the treatment of obesity, certain forms of neuralgia of unknown origin, and of gout, for example, the strict diet had rendered effective aid in many instances. In the field of dietetic therapy, in particular, radical changes of diet frequently supplied essential factors or eliminated deleterious ones in most welcome and unexpected ways.

**The Mechanics of Some Digestive Processes.**—Prof. W. B. Cannon of Harvard University discussed this phase of the subject, and illustrated his remarks with stereopticon views of *x*-ray slides, which showed with great clearness the presence of various foodstuffs in the stomach and intestines. He also exhibited a number of tissue paper tracings of these shadows of food in the intestine. These studies had been undertaken in order to ascertain how the different foodstuffs were treated mechanically in the stomach and intestine, and at what rate they left the stomach. It was found that the carbohydrates, which did not unite readily with the free acids of the stomach, and which were not materially affected by the gastric juice, made a quick exit; the proteids, which united with the free acids of the stomach, made a comparatively slow exit, and fats, which checked the secretion of acid, made a still slower exit. It was also observed that the presence of fats delayed the exit of both carbohydrates and proteids. Under normal conditions, the carbohydrates remained in the stomach only about half as long as the proteids. Evidence had accumulated to show that the alternate opening and closure of the pylorus was controlled by the presence of a certain amount of free acid in the stomach. This caused the pylorus to open, and then, as the acid chyme passed from the stomach into the duodenum, its acid content closed the gate behind it, but as this acid became neutralized by the alkaline secretion of the pancreas, the closure of the pylorus weakened until the acid in the stomach again opened it. In this way the process was continually repeated.

**The Influence of Preservatives and Coloring Matters and Their Relation to Nutrition.**—Dr. Harvey W. Wiley, Chief of the Bureau of Chemistry, U. S. Department of Agriculture, said the widespread use of preservatives and coloring matters in food products had attracted the attention of physiologists and food officials during the last few years. Two important questions were involved in the use of these bodies in food products: one related simply to the question of fraud or deception, and the other related to the influence of those bodies upon health and digestion. There were many food products which were prone to decay; therefore, when they were presented in a well preserved state, it was reasonable to infer that they were fresh. If that freshness was retained for an indefinite time by the addition of chemical preservatives, it was to that extent deceptive. The chemical preservatives referred to were not those of a condimentary nature, such as salt or sugar, etc., which always revealed their presence by the odor or taste. On the other hand, they were those of a non-condimentary nature, which had neither odor nor taste. Their presence, therefore, in food products was not announced to the consumer in any way unless it was by the label upon the foods themselves. Therefore, *a priori*, the use of dyes and preservatives in foods was reprehensible, aside from their influence upon health. In regard to the latter point, the most conflicting views obtained. Numerous experiments had been made in various countries, and from the results of those experiments opposed conclusions had been drawn. Dr. Wiley said his own experience led him to believe that the use of even small quantities of ordinary preservatives for a long while, or large quantities for a short while, led to unfavorable effects. There was, in general, a loss of weight, a feeling of lassitude and malaise, and in some cases more pronounced symptoms of intestinal and metabolic disturbance. In all cases the same general results were produced. Some of the preservatives commonly used in foods, such as borax, acted more vigorously and promptly than others, such as benzoic and salicylic acids. In fact, these latter seemed to have the least injurious effect of the ordinary preservatives employed. Of the coloring matters used, the speaker said he had only experimented with one, namely, sulphate of copper, and the results of his work did not permit him to say anything very good of that very common and wholly unnecessary coloring agent. In conclusion, Dr. Wiley said he thought there was no necessity for the use of chemical preservatives in food products. There were other methods at our command that were unobjectionable, providing the food was not preserved too long. Among those methods he mentioned cold storage, sterilization and dessication. By their use food products could be preserved from one season to another, which, excepting for unusual purposes, was long enough. They were certainly preferable to the indiscriminate drugging to which the public was now more or less subjected. The prescribing of drugs should be left to the medical profession, and not to the manufacturer of foods. The pharmacopeia and the grocery store should be kept separate.

Prof. Carl von Noorden of Frankfort, who was invited to open the discussion, simply thanked those who had taken part in the symposium for their interesting and instructive papers.

Col. Valery Havard, Asst. Surgeon-General, U. S. A., and late medical attaché with the Russian Army in Manchuria, made some remarks upon the ration of the Russian and Japanese soldiers in the field, and its effect upon their health and efficiency. He stated that the lesson of the advantages of frugality in diet so convincingly taught by Prof. Chittenden had never been so impressively demonstrated as during the Russo-Japanese war in Manchuria. Both Russian and Japanese soldiers were fed on rations which American and English soldiers would have rejected with scorn, and yet, for rugged health, strenuous work and endurance of hardships during a long winter's campaign, he doubted whether they had ever been excelled. The Russian ration in the field consisted of about two pounds of black rye bread, fourteen ounces of fresh meat, three or four ounces of cereals or grits, some vegetables, and tea and sugar. These quantities of food were often reduced in emergencies. The black bread was not very palatable to the American taste, and probably not very nutritious, but it possessed valuable laxative properties, so that constipation was unknown in the Russian army. Each company had an ambulant or traveling kitchen, on wheels, drawn by two horses; it consisted chiefly of a huge boiler, with a furnace underneath. Wherever the company went, the kitchen followed, and while on the march the dinner was cooking and could be served as soon as the company stopped to make camp. All the constituents of the ration, with the exception of the bread, were put into the boiler, and the result was an excellent soup. The soup, with whatever vegetables it contained, being eaten, the meat was then forked out from the boiler, sliced, and distributed as a second course.

The Japanese soldier's rations consisted of about a quart of rice, half a pound of fresh fish or meat, some vegetables, and tea. When going into a fight he received, instead, an emergency ration consisting of cooked rice, or hard tack, and a four-ounce can of beef. In the health condition of both the Russian and the Japanese troops, the experience of all former wars had been completely reversed; instead of

the mortality from disease greatly exceeding that from wounds, it was found to be much less. In the Russian army there had been no epidemic of any kind, no prevalent camp disease, and yet infectious germs were not lacking. There were always cases, not only of typhoid fever, but also of typhus, recurrent fever, dysentery and anthrax; yet these diseases never spread beyond the sporadic stage. The health of the Japanese troops, according to all accounts, was also eminently satisfactory, and would have been at least as good as that of the Russians were it not for beriberi, from which they were said to have seriously suffered, making up at least three-fourths of their morbidity. The cause of beriberi had not yet been exactly determined; the former belief that it was due to an exclusive vegetable diet, such as was used in countries where this disease prevailed, had been abandoned.

Maj. Louis L. Seaman, late Surgeon First Regiment of Engineers, U. S. Volunteers, said he was specially interested in the remarks of Prof. Cannon on the mechanics of certain processes of digestion. His elucidation of the subject was so clear that one could not help regretting he had not gone further afield, leaving the paths of physiology for those of pathology, and told something of the results of the use of a defective dietary. In other words, on the effects of a diet that no longer acted as a food, but as an irritant or a foreign substance, and so became a factor in the mechanical production of disease. It was that cause that contributed largely to bringing the American army almost to its knees in its short campaign in Cuba and Porto Rico in 1898, when whole regiments were suffering from diarrheas and intestinal catarrhs. During the Russo-Japanese war, in the siege of Port Arthur, the besieged Russians were compelled to subsist on a diet without vegetables, and they rapidly succumbed to the ravages of scurvy, 9,003 cases being found in the fortress when it capitulated. The Besieging Japanese, living on a diet almost exclusively of vegetables, chiefly rice, deficient in its nitrogenous nutrition, had their ranks seriously decimated by beriberi.

Dr. Graham Lusk, who closed the discussion, confined his remarks chiefly to Dr. Folin's paper on protein metabolism.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 21, 1905:

| | Cases | Deaths |
|---|---|---|
| Measles | 113 | 2 |
| Diphtheria and Croup | 218 | 28 |
| Scarlet Fever | 75 | 6 |
| Smallpox | .... | ..... |
| Chickenpox | 35 | ..... |
| Tuberculosis | 326 | 151 |
| Typhoid Fever | 99 | 17 |
| Cerebrospinal Meningitis | 10 | 8 |
| Typhus Fever | ..... | ..... |
| Yellow Fever | ..... | ..... |
| Cholera | ... .. | .. ... |
| Totals | 876 | 212 |

**Bronchopneumonia in the Eighth Month of Pregnancy; Spontaneous Delivery; Abscess; Recovery.**—Hirigoyen reports the case of a patient thirty-four years old. In the eighth month of her tenth pregnancy she was attacked with severe bronchopneumonia. Ten days after the beginning of her illness she gave birth to a child, which died the next day. The mother became worse and worse, although there was no disturbance in the genital apparatus. On the eighth day the patient's condition was so grave that the case was considered hopeless; treatment had availed nothing. Hirigoyen then decided to make an injection into the thigh of one gramme of the essence of turpentine. This had no effect; but a second injection, two days later, was followed by an immediate reaction, which terminated in the formation of an abscess. From this moment the patient's condition improved. In two days the abscess was opened and pus was taken out. Three days later the patient became convalescent. At the end of two weeks she had entirely recovered.—*La Presse Médicale.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the period from October 9 to 20, 1905:

### ANTEPARTUM MEASUREMENT OF THE FETAL HEAD.*

By WILLIAM S. STONE, M.D.,
NEW YORK.

THE inability of the obstetrician to make sufficient practical use of his knowledge gained from pelvimetry has long been recognized as due to the lack of precise methods for the determination of the relative size of the head and the pelvis. Various procedures have been tried, but, with the exception of the Müller method of manual engagement of the fetal head by means of suprapubic pressure, none has proven of sufficient accuracy to be generally adopted.

The Müller method is certainly of great value, increasing proportionately to one's experience, and has been of distinctly more service to the writer, since it has been used in conjunction with the method, to be described, of directly measuring the head through the abdominal wall.

This method of measurement of the fetal head may be regarded as a simplification of that described by Perret, who used a specially devised instrument, and, after measuring the head, pinched up a fold of the abdominal wall between the fingers, measured its thickness, and deducted the amount from the fetal measurement.

Edgar (The Practice of Obstetrics), who quotes Perret's own description of his method, says that it has been in constant use in the Tarnier clinic for a number of years, and, although numerous published reports of results exhibit great diversity in regard to the practical utility of the instrument, he thinks, in the hands of one specially trained, cephalometry may be termed a practical success.

Norris (*American Journal of Obstetrics*, 1904, vol. I., No. 3, p. 389), however, says this method cannot be relied upon, and considers the Müller method more valuable.

The writer uses the ordinary pelvimeter, and does not deduct anything for the thickness of the abdominal wall, because in most instances the wall is surprisingly thin during the last months of pregnancy, as can be attested by those who have performed cesarean sections. It is also recognized that skill in abdominal palpation is necessary, but those cases, in which accurate knowledge of the relative size of the head to the pelvis is required, demand special skill, both in the diagnosis and in the treatment. Accurate pelvimetry, too, requires long experience and skill.

The comparative ease with which the fetal head is ordinarily palpated, especially during the last months of pregnancy, led the writer to attempt to directly measure the occipitofrontal diameter through the abdominal wall in the following way: The patient is placed in the ordinary dorsal position for an abdominal examination, and the examiner, standing by the side and facing the lower end of the patient's body, first carefully palpates and makes out the position of the head. If it is already engaged in the pelvis, it will not be practicable to measure it, but in such cases it naturally is unnecessary. In a few instances, however, the writer has had the head pushed up by an assistant, so that it could be measured for the sake of practice. The occipital and frontal poles are then grasped between the two hands, and an assistant places from below the ends of the pelvimeter between the terminal phalanges of the middle and ring fingers of the examiner, pushing them firmly inward, as the examiner directs. It is essential that the ends of the pelvimeter go between these fingers, because in palpation one naturally places the middle or longest finger nearest the two poles from which the measurements are to be taken. If placed in front of the middle finger, the pelvimeter will slide forward and the measurement will be inaccurate. An assistant or nurse is necessary to obtain the best results, in order that the examiner's fingers may be entirely free to accurately locate the fetal parts.

The writer, by this method, has been able to measure forty-one cases in the service of the New York Lying-in Hospital during the past year and verify the results by examination after delivery.

TABLE I.

| No. | A P. | Head. Post P. | | Pelvis. | | Labor. |

| 40 | 11.75 | 11.75 | 7.25 | ..... | ..... | " |
| 41 | 10.00 | 10.00 | 8.50 | 12.00 | 10.00 | " |

Table I shows the detailed results. Most of the cases were admitted just before or during labor. In a few instances it was possible to make some observations in regard to the increase of size of the fetal head during the late weeks of pregnancy.

Small heads, with rather an excess of liquor

*Accepted as thesis for admission to the American Gynecological Society, May, 1905.

amonii, were the hardest to measure, because of the difficulty of fixing them between the hands while the pressure was being made with the pelvimeter.

The table will show that in twenty-eight instances the postpartum measurement of the occipitofrontal diameter agreed exactly with the measurements made through the abdominal walls before labor; in eleven there was an error of 0.25 cm.; in two of 0.50 cm.

Any personal bias was eliminated in many instances by turning the scale of the pelvimeter downward so that it could only be read by the assistant or nurse. The resident surgeon, Dr. E. McDonald, who assisted the writer with most of the cases, often measured them independently with as much accuracy as did the writer.

It was then necessary to decide, if possible, upon some average amount to deduct from the occipitofrontal diameter in order to estimate the biparietal.

The skulls of one hundred new-born children were specially measured for this purpose, with the result shown in Table II.

TABLE II.

| OF. diameter. | No. cases. | Average difference |
|---|---|---|
| 10.00 | 1 | 1.00 |
| 10.50 | 4 | 1.55 |
| 10.75 | 8 | 1.81+ |
| 11.00 | 17 | 1.91+ |
| 11.25 | 21 | 2.07+ |
| 11.50 | 19 | 2.26+ |
| 11.75 | 9 | 2.50 |
| 12.00 | 13 | 2.30+ |
| 12.25 | 5 | 2.35 |
| 12.50 | 1 | 2.50 |
| 12.75 | 2 | 3.12+ |
| | 100 | 2.33+ |

The average difference in the two diameters for the entire one hundred cases was found to be 2.33 cm., but that it varied fairly constantly with the size of the head, the smaller heads showing in general less of a difference than the larger ones. If 2 cm. is deducted for the heads with an occipitofrontal diameter of less than 11 cm. and 2.50 cm. for those above this measurement, fairly accurate results will be obtained and sufficient amount will be allowed for the moulding.

Perret, quoted by Edgar, gives the average difference in the two cranial diameters for the seventh, eighth, and ninth months in all skulls having a biparietal from 7.62 cm. to 8.89 cm. as 2.54 cm. According to Williams there is an average difference of 2.50 cm.

The amount of diminution in the diameters that is possible from moulding is naturally somewhat of an uncertain factor, but probably, depending upon the size and hardness of the head, does not average over 0.50 cm. or 0.75 cm. Two experiments relative to this showed the following: A large head with an occipitofrontal diameter of 12 cm. under moderate pressure with the forceps moulded 0.50 cm.; under hard pressure, 0 75 cm.

An average head with an occipitofrontal diameter of 11.25 cm. moulded 0.75 cm. under moderate pressure, and 1 cm. under hard pressure. The bones overlapped in each experiment.

Table I., in which both the cranial and pelvic measurements are given shows a disproportion between the biparietal and the conjugate vera rarely exists in cases which subsequently have a normal labor. Such a disproportion followed by a normal labor occurred in two of this series of cases.

Case No. 7 gave a history of previous tedious labors. The occipitofrontal diameter measured 11.50 cm. before delivery, and the internal diagonal diameter of the pelvis only 10.50 cm. from which a conjugate vera of 8.50 cm. was estimated. The pelvis, however, was that variety of flat pelvis with a markedly jutting promontory, and with considerable room upon either side. The decision to allow her to attempt her own delivery, especially in the presence of strong uterine contractions, was justified by the subsequent normal course of the labor.

Case No. 22 showed only a disproportion of 0.25 cm., and in the presence of external measurements that were above the average size the decision to allow her to deliver herself was not particularly hard to reach. It should also be noted that in neither of these cases did the Müller method of suprapubic pressure favor a policy of non-interference.

The practical utility of the measurements, in which greater difficulties were presented, are shown in the following five cases:

Case No. 20. Aged eighteen years, I-para. Admitted in the first stage of labor. Head in L. O. A. position and floating above the brim.

The Müller method gave a negative result. The pelvic measurements were: Spinæ, 20; cristæ, 22; obliques, 19.50; external conjugate, 19.50; internal diagonal conjugate, 11, from which the true conjugate was estimated to be 9.50. Justominor pelvis. The occipitofrontal diameter measured through the abdominal wall 11.25 cm. After three hours of full dilatation the high application with Tarnier axis traction forceps was made and the delivery of a living child accomplished. The occipitofrontal measured 11.50 cm., or 0.25 cm. more than was estimated prior to delivery. The biparietal measured 9.25 cm. Total length of the child 49 cm.; weight, 3050 grammes. A disproportion of 0.25 cm. was thus overcome, although with considerable difficulty, by the moulding.

Case No. 17. Aged seventeen years, I-para. Admitted at the beginning of labor. Head in L. O. A. position and floating above the brim. The pelvic measurements were: spinæ, 20; cristæ, 24; obliques, 20.50; external conjugate, 18; internal diagonal conjugate, 10.50, from which the true conjugate was estimated to be 8.50. Justomino pelvis, with flattening. The Müller method, although doubtful, seemed rather favorable to the application of forceps. The occipitofrontal diameter measured 12 cm. and the head seemed very hard. Efforts with the forceps were unsuccessful, and a cesarean section accomplished the delivery of a living child. The occipitofrontal diameter measure ured 12 cm. the same as before delivery, but the biparietal was 10 cm., making a disproportion of 1.50 cm. Child's total length 50 cm. and weight 3750 grammes.

Case No. 37. Aged thirty years, IV-para. Admitted just before labor. Three previous labors had been instrumental and children were stillborn. Head floating above the brim. Müller method showed that engagement was improbable. The pelvic measurements were: spinæ, 22; cristæ 28; obliques, 21; external conjugate, 18; internal diagonal conjugate, 9.50, from which the conjugate vera was estimated to be 7.50. Flat rachitic pelvis. The occipitofrontal measured through the abdominal wall 11.75 cm., from which the biparietal was estimated to be not less than 9.25 cm. A living child was delivered by cesarean section. The occipitofrontal after delivery measured 11.50 cm., 0.25 cm. less than the measurement before labor, but the biparietal was 9.25 cm. making a disproportion of 1.75 cm. between the biparietal and conjugate vera.

Case No. 16. Aged thirty-three years, II-para. Patient said that she was two weeks past the expected date of her labor. Previous labor was tedious. The head was floating above the brim,

and appeared to be large and hard. Suprapubic pressure failed to engage the head.

The pelvic measurements were: spinæ, 24; cristæ, 27; obliques, 21; external conjugate, 19; internal diagonal conjugate, 10.75 from which the conjugate vera was estimated to be 8.75. The occipitofrontal diameter measured through the abdominal wall 12.50 cm., from which the biparietal was judged to be at least 10 cm., or 1.25 cm. more than the conjugate vera. Labor was immediately induced by means of the Champetier de Ribés bags, but, as no engagement of the head occurred after full dilatation and rupture of the membranes, cesarean section was performed with the delivery of a living child, weighing 4100 grammes and having a total length of 51 cm. The occipitofrontal diameter measured the same as was estimated before delivery, and the biparietal 10 cm.

Another case, not in the table, with a markedly flat, rachitic pelvis, was judged by a colleague to demand a cesarean section. The writer estimated the biparietal from the occipitofrontal measurement to be the same as the conjugate vera, and thought the patient could deliver herself, which she promptly did on the way to the operating room for the proposed cesarean.

With no maternal or fetal mortality in this series of cases, it seems as if, at least in the special cases thus described, these measurements were of real practical value. They should be considered in the same relation to diagnosis and treatment in obstetrics as clinical microscopy is to general medical diagnosis and treatment, sometimes furnishing positive information, at other times only corroborative assurance. Due consideration must always be made of the other data furnished by the previous history, age of the patient, and other physical signs.

The Müller method of suprapubic pressure in two instances rather negated the measurements. on account of which, in Case No. 18, high forceps was attempted before resorting to cesarean section.

The apparent hardness of the head, and the variety of pelvis rather than the absolute degree of contraction of the internal conjugate, furnished the most efficient aids to a proper interpretation of the figures obtained from the measurements.

There were about 150 deliveries in this service during the time in which these measurements were taken without any fetal mortality, except in one instance; a patient, who died a few hours after admission from eclampsia, gave birth to a dead six and one-half months' fetus.

Apart however, from those cases first coming under observation at full term or during labor, the measurements will be found to have their greatest utility in furnishing information earlier in pregnancy as to whether it should be allowed to continue to full term and cesarean section be performed, or if not, as to the proper time for the induction of a premature labor.

The conclusion of Norris, in a paper entitled "The Ultimate Results of Induced Labor for Minor Degrees of Pelvic Contraction" (*Amerian Journal of Obstetrics*, 1904, vol. I. No. 3, p. 389) that it is extremly important to be sure that the child is large enough, has been confirmed by the writer in several instances. A premature child is unable to withstand the shock of a possible operative delivery, or if born alive, to withstand the first few weeks of its extrauterine environment as well as the one born at full term.

The following most discouraging case occurred in the writer's service before he had begun his antepartum measurements:

Patient aged twenty-seven years, II-para. Admitted in the early part of the seventh month of her gestation. Previous labor was difficult and child was stillborn. The pelvic measurements were: spinæ, 20.50; cristæ, 35; obliques, 20.50; external conjugate, 16.50; the internal diagonal conjugate, 10, from which the conjugate vera was estimated to be 8. The height of the fundus corresponded to the menstrual history. The head was small, compressible, and efforts to make it engage seemed successful until the middle of the seventh month. Labor was then induced by means of the Champetier de Ribés bags. No engagement occurred after full dilatation, and a podalic version and extraction accomplished the delivery with some difficulty. The child gasped a few times, but respiration could not be established. Its length was 47 cm., the occipitofrontal diameter 10.75 cm. and the biparietal 9 cm. If the writer had been in possession of the same information he has subsequently derived from the antepartum measurements of the fetal head, he would have known that with an occipitofrontal of 10.75 cm. there were great chances of the biparietal being at least 0.75 cm. more than the conjugate vera. The amount of delay in the delivery of the aftercoming head in this case was not sufficient to have jeopardized the life of a full term child. This case then should have been either induced earlier, or possibly better, allowed to go to full term and have a cesarean section performed.

The following case, in contrast to the preceding one, was treated three months later with the additional knowledge gained from the measurements: Age twenty-eight years, IV-para. First two labors were operative and children were stillborn. The writer delivered a live child by cesarean section at the end of the last pregnancy. The pelvic measurements were: spinæ 22.50; cristæ, 27.50; obliques, 21; external conjugate, 18; internal diagonal conjugate, 10.75; from which the conjugate vera was estimated to be 8.75. The pelvis was flat and funnel-shaped. The occipitofrontal measurements of the last child delivered by cesarean section was 12.50 cm.; the biparietal 10 cm. She first presented herself at the sixth month of her present pregnancy, but the head was too small and movable to accurately measure The occipitofrontal measured at the seventh month 9.50 cm., at the eighth, 11 cm., when she was told to enter the hospital for an induction. She delayed doing so for ten days, so that at the time induction was started it measured 11.50 cm. Labor was induced with the Champetier de Ribés bags, and delivered by a difficult podalic version and extraction of a living child whose occipitofrontal diameter measured 11.50 cm., the same as estimated before delivery, and the biparietal 8.50 cm. Its length was 49 cm. and weight 2500 grammes. If she had entered the hospital at the time directed, ten days before she did, the delivery would not have been so difficult.

A more complete knowledge of the rapidity of growth of the head during the last two months of pregnancy will be of inestimable advantage in the determination for the proper time for induction. The writer's efforts to work out this problem have been limited to the following measurements: An increase of the occipitofrontal diameter of 0.75 cm. in three weeks; 3 cm. in two months; 1 cm. in two weeks; 0.50 cm. in nine days; 0.50 cm. in twelve days. However near these few observations may approach the average rate of increase during the last few weeks, the writer feels sure that the increase of the hardness is a more im-

portant factor in the last ten days, and the field for the induction of labor at the middle of the last month is very much wider than is generally accepted.

These measurements, showing that an occipito-frontal diameter of 11 cm. assures a sufficiently large child, will enable one to more definitely select the proper time for induction.

*Conclusions.*—1. The antepartum measurement of the fetal head is as feasible, at least for the specially trained, as is pelvimetry.

2. The measurements afford a more precise method of estimating the course of labor in contracted pelvis than any other now available.

3. They are of the greatest volue in the selection of the cases suitable for premature induction, and in the determination of the best time for performing it.

## CARCINOMA OF THE INTESTINAL TRACT.*

By JAMES P. TUTTLE, M.D.,
NEW YORK.

In a statistical paper read before this Association in 1901 on malignant neoplasms of the large intestine (*New York State Journal of Medicine*, June, 1902, page 169), it was shown: (1) That cancer comprises over eighty per cent. of all neoplasms in the human body. (2) That about fifty per cent. of all cancers are found in the gastrointestinal tract. (3) That while cancer is ostensibly a disease of mature age, it is being found more and more frequently between puberty and thirty years, and consequently youth cannot always be accepted as a positive diagnostic contraindication to the presence of this disease. (4) That cancer is on the increase throughout the civilized world, especially cancer of the intestinal tract. (5) That local examination with the sigmoidoscope and early exploratory laparotomy are the only means of positive diagnosis in malignant disease above the reach of the index finger. And (6) that while the *x*-ray, radium, and the chemical cautery have proved efficacious in certain superficial or skin cancers, early resort to radical surgery is the only hope for those afflicted with internal malignant growths.

Experience and the published statistics of the past four years serve only to confirm each of these conclusions. The death rate from cancer all over the world has shown a marked increase in every quinquennial period for the past thirty years, and, in view of the fact that we are absolutely without any preventive methods, it is to-day the most discouraging and alarming proposition with which the medical profession has to deal. In connection with this general increase, it is a significant fact that cancers of the intestinal tract have increased out of all proportion to those of other portions of the body; a fact, which lends color to the belief of some that these growths have their origin in vegetable parasites which are taken into the system through the alimentary tract, naturally invade the first tissue, offering a suitable field for their development, that field usually constituting a traumatized or abraded surface. Weinberg and Gasper (*Zeitschrift für Krebsforschung*, B. 1, H. 2, 1904), in a study of the vital statistics of Stuttgart for the past thirty years in decennial periods, have brought out the following facts: (1) Increase of cancer in general. (2) Increase of cancer in proportion to other diseases. (3) Increase of cancer in the digestive tract compared with other regions. (4) The general increase in cancer is practically made up by the increase in that of the alimentary tract. From 1873 to 1883 there were 556 deaths from cancer in the alimentary tract, and 372 from cancer in other organs; from 1893 to 1903 there were 1,005 deaths from cancer in the alimentary tract, and 382 from cancer in other organs; showing an increase of ten, .027 per cent., in cancer of other organs, to 449, 81 per cent., in that of the alimentary tract. (5) The increase was relatively greater among males, especially so far as sarcoma is concerned.

Had these statistics been made from the clinical histories it might be stated that the modern methods of examination had rendered the diagnosis more feasible, and thus larger numbers of intestinal carcinoma were being discovered than formerly; the fact, however, that the statistics are drawn from autopsies in the various periods, so that the recognition of the disease was just as feasible in 1873 as it is to-day, shows clearly that the proportionate increase of cancer is an actual, and not an apparent, fact. Without going into the statistics and the details of our studies, it is sufficient to say that the vital statistics of England and America practically prove the same state of affairs in these two countries. If this proportionate increase continues, the time is not far distant when there will be more deaths in these countries from cancer than from tuberculosis, diphtheria, and typhoid fever combined. These facts render a special study of cancer in the alimentary tract of the utmost importance, not only to the medical profession, but to the whole civilized world.

*Site.*—The comparative frequency with which cancer attacks the different portions of the alimentary tract from the stomach downward is: 1, stomach; 2, rectum; 3, sigmoid; 4, cecum and ascending colon; 5, the transverse and descending colon; 6, vermiform appendix; 7, duodenum; 8, ileum; 9, jejunum. Figures drawn from many sources amply prove this order of occurrences, and yet I am convinced they are misleading, so far as the actual proportions are concerned. For instance, in my study on this subject, I have collected, all told, reports of 2,432 malignant tumors of the intestinal tract, exclusive of the stomach, of which 1,690 were cancers of the rectum, 182 cancer of the sigmoid, 160 cancer of the transverse and descending colon, 283 cancer of the cecum and ascending colon, 60 cancer of the vermiform appendix, 37 malignant neoplasm of the ileum, of which 27 were sarcoma, 14 neoplasm of the jejunum, of which 12 were sarcoma, and 8 malignant neoplasm of the duodenum, of which 1 was sarcoma. I do not imagine for an instant that the proportion of cancer of the rectum could be maintained in a complete collection of all malignant tumors of the intestinal tract, for many of the cases included in my own studies have never been published, having been furnished me through private reports in answer to a circular sent out to the profession some seven years since, and I have no doubt there are just as many unpublished cases of cancer of other organs; but, in general, this order of occurrence will be maintained.

The *types of the neoplasms* found in the intestinal tract include cylindrical epithelioma, adenocarcinoma, medulary carcinoma, scirrhus and colloid cancer, and sarcoma of the round, spindle, and mixed cell varieties; of these the adenocarcinoma is by far the most frequent; it occurs in the rectum throughout the large intestine and in the duodenum; in fact, wherever glandular tissue exists. Pure epithelioma is very rare, except at the margin of the anus and just within the rectum. The medullary cancer may occur at any part of the intestinal

*Read at the twenty-second annual meeting of the New York State Medical Association, October 16-19, 1905.

tract, but is much more rare than the adenocarcinoma. Scirrhous cancer rarely occurs in the rectum; it is found, however, in the sigmoid and other portions of the colon, except in the cecum; also in the small intestine and the duodenum. Sarcoma is prone to occur in the small intestine rather than in the large; many of the cases reported as sarcoma of the cecum being, in fact, sarcoma of the Bauhinian valve, which is practically a part of the ileum and not of the large intestine. Sarcoma has been seen, however, in the large intestine, even as low down as the margin of the anus.

The *symptoms* of malignant growths in the alimentary tract vary according to the site at which the growth occurs, the character of the neoplasm, and the state of its development. The symptoms of this disease in the different portions of the intestinal tract vary so greatly that it is necessary to treat the several divisions almost as separate organs. For example, the subjective manifestations of malignant disease of the duodenum are so closely allied to the symptoms arising from diseases of the stomach that it is often almost impossible to distinguish between the two; while those of the jejunum and ileum are practically the same as those arising in diseases of the transverse and descending colon. We must, therefore, treat these portions of the small intestines separately.

*Duodenum.*—The symptoms of cancer in this portion of the intestine, as already stated, are largely stomachic and vary according to whether the growth involves the lower or middle portion. They always begin in disturbances of digestion, loss of appetite, eructations, nausea, vomiting, increasing pain in the epigastric region, dilatation of the stomach, with splashing when full of fluid, loss of weight and strength, anemia or cachexia in the later stages, and irregular action of the bowels. Constipation is usually spoken of as one of the symptoms, but I exceedingly question if it is any more than a compensatory constipation, dependent upon the small amount of food ingested and passing into the intestinal tract. The patients whom I have seen have all complained of griping and desire to go to stool without efficient result. If the growth is above the papilla of Vater there will be eructations of the stomachic fluids, acid, watery, and containing no bile; if the growth is below the papilla the eructations and vomit will contain bile in greater or less quantities; if at the site of the papilla the eructations may or may not contain bile (they usually do not), the vomiting will be less severe, and one will find in the stools a large proportion of undigested fats and starches. Pic claims that it is almost impossible to diagnose cancer in this portion of the intestinal tract from that of the pancreas, but the absence of sugar in the urine is such as to warrant the positive exclusion of pancreatic involvement. Blood may or may not be present in the vomit. It does not come from the neoplasm except in very late stages, but may be due to rupture of capillaries from straining. Pain is an uncertain symptom; some patients suffer intensely while others have only a vague discomfort. The presence or absence of hydrochloric acid in the vomit is important in distinguishing between disease of the duodenum and the stomach. Increasing nausea and tendency to vomit are the most important subjective symptoms; they indicate to the practitioner the possibility of what is developoping at a time when it is possible to do something radical and curative. The objective symptoms are tension of right rectus muscle; flat or hollow abdomen; the presence of a tumor, irregular, nodular, always immovable and slightly painful on pressure in the right epigastrium. Unfortunately, however, the tumor is often impalpable until the disease has progressed to such a state that operation is exceedingly hazardous. Especially is this true in stout persons. With all the skill of our erudite diagnosticians it is often impossible to differentiate growths of the duodenum from gallstone, cholecystitis, and diseases of the pancreas without surgical exploration, and it is a dangerous waste of valuable time to postpone such exploration until the patient has grown so emaciated or the tumor so large that it can be felt. Only in the very last stages of the disease do the stools show blood, pus, or mucus; their examination is therefore of negative value in diagnosing the case. Early recognition of the probability of a growth and prompt resort to surgical exploration and extirpation, if the growth is found, offer the only hope in this disease.

*Jejunum and Ileum.*—Cancer of these portions of the small intestine produces no subjective symptoms upon which a positive diagnosis can be made until late in the disease. They are frequently the same as the symptoms found in diseases of the transverse and descending colon; they begin usually in irregular griping pains followed by increased visible peristalsis, frequent desire to go to stool or pass wind, with more or less digestive disturbances, loss of appetite and flesh, and symptoms of autointoxication. Cachexia and alternating diarrhea and constipation come on in the latter stages; local or general peritonitis may be due to extension of the disease, and death will occur from perforation, sepsis, or exhaustion. The tumor is rarely palpable in its early stages, and if so, it is always *exceedingly movable* and hard to grasp or hold in one position. If the growth is of the scirrhous type, the stools rarely contain any blood, pus, or mucus, except in the very last stages. On the other hand, if the growths are of the medullary or adenocarcinomatous type, mucus, blood, and pus may be found in the stools during a comparatively early period of the disease. The blood in the stools, when the small intestine alone is involved, will usually be found disintegrated and black, of a coffee ground nature, rather than fresh and in clots. Tympanites may or may not exist, but a diagnostic feature of some importance consists in the fact that the cecum and colon are not distended, but retain their normal resonance.

*Ascending Colon and Appendix.*—The symptoms of cancer in this region of the intestine are practically those of chronic appendicitis. They consist in mild disturbances of digestion, flatulence, loss of appetite, constipation, increasing tenderness over the right hypochondriac region, and tension of the right rectus muscle. When the growth involves the appendix alone it is impossible to determine its nature by any other means than exploratory incision. The temperature is always more or less elevated, especially when the tumor is well advanced. The variation in temperature is very liable to lead one to the conclusion that he has to deal with a simple chronic appendicitis, and valuable time is likely to be wasted in waiting for a period of complete quiesence before resorting to operative procedure.

*Transverse and Descending Colon.*—The symptoms of cancer in this portion of the intestinal tract are frequently the same as those detailed for the ileum and jejunum. They always begin with griping and a tendency to diarrhea without any increase in the discharge of fecal matter or blood in the stools. If the tumor is in the transverse colon, sagging downward and displacement of this organ is likely to occur. This displacement, however, is so frequent

in connection with other conditions that one would hesitate to accept it as a strong indication of malignancy. One symptom, however, to which I would call your attention is the temporary arrest of gases at this particular portion of the abdomen. Patients often complain of tenderness at certain locations, and if their attention is called to the fact they will observe that their tenderness is enhanced by the accumulation of gases about that point and often suddenly relieved by a gurgling sensation there and the subsequent passage of gas from the intestinal canal. I have no statistics that absolutely confirm the fact, but I am inclined to think that a markedly increased tendency to expel gas and inability to retain it is one of the earliest symptoms of malignant disease of the colon and sigmoid flexure. Along with this passage of gas, early in the disease, there appears in the stool a certain amount of glairy mucus; this symptom is common to neoplasms of the entire colon, including even the rectum. This mucus is always glairy and never coagulated as in typical mucomembranous colitis. In my own experience I have never seen a single case of carcinoma of the colon in which there was a discharge of the typical coagulated and membranous shreds. In one case these shreds were observed in a case of carcinoma of the pancreas and mesentery, but the colon itself was not involved in the disease. Constipation, or rather obstipation, alternates with attacks of diarrhea, the discharge of pus, blood, and carcinomatous shreds if the growth be of the adenocarcinomatous or medullary types, and of blood with very small quantities of pus if it be of the scirrhous or sarcomatous varieties, but it should always be remembered that constipation is a late and not an early symptom of cancer. Diarrhea or frequent desire to go to stool with no effectual results is the striking early symptom of cancer of the colon.

*Sigmoid and Rectum.*—The symptoms of cancer of the upper sigmoid are largely the same as those already given for the descending colon, but those of disease of the lower portion of the sigmoid resemble so closely the symptoms of cancer of the rectum that the two portions may practically be considered as one. The disease in this location is nearly always preceded by habitual constipation; the histories of patients show a resort to cathartics long before there was any possibility of obstruction to the passage of fecal matter by the neoplasm. This constipation is, in my opinion, much more frequently the cause than the result of the neoplasm; the early symptoms of the disease will always be found in an increased desire to go to stool, griping, and bearing down without adequate result. This symptom leads to the employment of enemata with a view to overcoming the supposed constipation, and frequently the first intimation that there is of organic trouble is the discharge of blood and mucus. Unfortunately, this symptom is too often attributed to the bursting of a hemorrhoidal vein and prescribed for accordingly, even by the best practitioners. The fact that hemorrhoids exist in nearly all such cases is very misleading and often leads to unwise treatment and unnecessary operations by those who do not make careful instrumental examinations of all cases in which there is discharge of blood, pus, or mucus with the stools. I have seen no less than ten cases operated on for hemorrhoids when there existed well marked neoplasms within four to seven inches of the anus. The discharge of glairy mucus, one of the first symptoms of the disease in the rectum and sigmoid, is often not noticed by the patient himself, as people are not prone to examine their stools carefully, and unfortunately when they do notice it and call the physician's attention to the fact, they are too often told that it is a matter of no moment and only the result of intestinal catarrh, for which they are treated without due consideration or proper examination.

Morning diarrhea, or, more properly speaking, call to stool immediately upon rising in the morning, associated with passage of mucus, blood, or pus is always a symptom of localized disease which demands the most careful digital and instrumental examination of the rectum and sigmoid. Happily for us and our patients the diagnosis of malignant disease of the sigmoid and rectum is now a possibility in its earliest stages through the systematic employment of the modern means of examination of these parts. The proctoscope, sigmoidoscope, and specimen forceps afford us an unfailing means of diagnosis in these cases, and we are not dependent upon the subjective symptoms of the patient to determine exactly what ails him. If the tumor is in the lower portion of the rectum within reach of the finger, it can always be diagnosed by the educated touch; if more than five inches from the anus, however, the instruments above mentioned are absolutely necessary and they should be resorted to without hesitation in every case of constipation or diarrhea observed, with or without the discharge or of any abnormal material in the stools. *Early diagnosis of the existence of malignant disease in the intestinal tract furnishes the only hope for individuals afflicted, and the sooner the profession recognizes the importance of early resort to instrumental examination in the lower portion of the bowel and exploratory incision higher up whenever subjective symptoms indicate the possibility of such growths, the sooner will we be able to reduce the mortality which now confronts us.*

The prognosis of cancer of the intestinal tract without surgical interference is absolutely hopeless. The fact, however, that metastasis and glandular involvement are later in this area than in any other portion of the body renders surgical interference more hopeful here than elsewhere. The one hope consists in early recognition of the condition to be dealt with, and this is why I have devoted my entire paper to diagnosis.

Time does not permit of the discussion of the various procedures in the treatment of these conditions; total extirpation is the ideal operation in all cases where this is feasible. I wish, however, to lay particular stress upon a point which I have elsewhere emphasized, namely, the importance of eliminating the fecal current from the involved area in cases where extirpation of the growth itself is impossible. It has long been customary and is still the practice of many surgeons to do an inguinal colostomy in cases of carcinoma of the sigmoid and rectum; if, however, there is sufficient healthy intestine below the growth to admit of anastomosis with healthy intestine above the growth, such a procedure is far preferable and is likely to result in a greater prolongation of life. Ileorectostomy and sigmoidorectostomy are far better procedures than colostomy. In inoperable cancer of the cecum or transverse or descending colon, ileosigmoidostomy is the ideal operation; if the growth involves the sigmoid then ileorectotostomy should be employed.

In inoperable exuberant carcinomatous growths low down in the rectum and filling up its caliber I have seen the most radical relief obtained by scraping away the growth with a curette and thoroughly cauterizing its base. I am persuaded that this procedure will prolong life quite as much as and obviate the disagreeable features of colostomy, although the latter should be done at the same time if the condition of the sphincters renders fecal continence imperfect.

In the small intestine and upper colon, whenever the growth is so mobile that it can be brought outside of the abdominal wall, it is safer to fasten it in this position, close up to the abdominal wound about it, and wait for two or three days before excising the growth. The operations thus far performed in this manner, eleven in all, with one death, render this procedure an exceedingly hopeful one as compared with the majority from resection followed up by end-to-end or lateral anastomosis. So far as the operations upon the rectum itself are concerned, I have nothing new to add to the statements made before this body in 1903. The mortality has been slightly reduced by modified technique, Dr. Swinford Edwards of London having recently reported 40 cases with a mortality of less than 9 per cent. Recurrences depend largely upon the site of the growth, the nearer the anal margin the more likely are they to recur; 90 per cent. of my recurrences have occurred in cases involving the lower two inches of the rectum, mostly operated upon by the anal or perineal route. I have had no recurrences so far in ten operations performed by the combined method; the mortality, however, in these cases (33 per cent.) is much greater than that by other methods; at the same time, I am persuaded that when the growth involves any portion of the rectum more than five inches from the anus, this is the method which should be employed.

42 West Fiftieth Street.

## THE QUICK CURATIVE TREATMENT OF GONORRHEA.

By FREDERICK A. LYONS, A.M., M.D.,
NEW YORK.

In the Medical Record of May 4, 1895, I published a series of fifteen cases of acute gonorrhea in the male, in which 67 per cent. were cured within six days, and almost 50 per cent. in three days or less, by a method which was described in full in that paper.

More than ten years have elapsed since that publication, so that I have more than followed Horace's injunction *"Nonumque prematur in annum,"* and at the present time I can report that out of a total of a little over 400 cases treated on that plan, in 384 of them or about 95 per cent., I have succeeded in curing the disease in six days, and in about 80 per cent. in twenty-four hours. When I say that the disease was cured in twenty-four hours, I mean that no gonococci were seen in the secretion at and after that time. It takes from five to ten days for the urethra to be restored to its normal condition. Of these 384 successful cases, 15 of them were primary attacks, and the results were as brilliant as in any of those in which there had been previous attacks.

As this paper was published so long ago, I am obliged to reprint here that portion of it which describes the plan of treatment.

When a patient presents himself complaining of symptoms pointing to a urethral difficulty, I first get a detailed history of the case, and then on examination of the penis, smear a little of the secretion, if there be any, on a cover-glass. If there be none, or but a slight moisture, I rub the sterilized platinum wire with a little loop on it over about three-quarters of an inch of the walls of the urethra a few times, and smear this on a cover glass. After staining in the usual way with methylene blue, I examine under an immersion lens. If gonococci are found and the history of the case shows it to be one of acute infection, and if there be a fair proportion of epithelial cells present in the secretion under the microscope, I deem it a good case for the quick curative plan of treatment, and proceed as follows:

Having had the patient urinate for the purpose of cleansing the canal, which I think is sufficient without further irrigation, I myself inject into the urethra, the patient being in the recumbent position, with an ordinary conical-shaped soft rubber pointed clap syringe, one drachm and a half of a 4 per cent. solution of nitrate of silver. I seize the meatus on removing the syringe, and hold the solution inside the urethra for from two to three minutes by the watch. The patient complains of no or but little pain at the time, and at most, according to my experience, a little smarting on urination during the next twenty-four hours, at the expiration of which time he is directed to present himself again. In the meantime he is cautioned to follow strictly the usual hygienic rules prescribed in these cases, and to do nothing more for himself whatever. When he presents himself again, it will usually be found that the character of the discharge has changed to a thin serous fluid, a little more abundant than it was before, and on smearing the cover-glass and examining, it will be found that the gonococci have entirely disappeared, or have been exceedingly reduced in numbers. If none are found, two or three more cover-glasses are smeared and examined to make sure of the fact, and nothing more is done. The slight inflammation will then disappear in the course of twenty-four or forty-eight hours, but the secretion of the urethra is examined for several days, until no more pus is present, and shows only normal epithelial cells, or as is sometimes the case, the ordinary bacteria that are commonly found in healthy urethræ.

If the gonococci have not entirely disappeared, the injection is repeated wiah a drachm and a half of a 2 per cent. solution of silver nitrate, and in twenty-four hours a reexamination is made. The second injection produces a little more pain afterward than the first, and the secretion the next day is more serous, and perhaps tinged with blood; but I have not yet found a patient refuse a third injection when I have deemed it necessary, with a 1 per cent. solution. If the gonococci have not entirely disappeared by this time, it is useless to proceed further, the treatment is abandoned, and the symptomatic plan pursued.

It will be seen that my present results are much better than those of my early report, and one explanation of this is that I have used the method only in those cases in which the aspect of the stained smear under the microscope gave me a reasonable assurance that success could be looked for. In other cases of acute gonorrhea coming for treatment, where the slide showed that, in my judgment, the disease had already progressed too far, the method was not employed, but other treatment pursued.

In 1895 I stated, as may be seen above: "If gonococci are found and the history of the case shows it to be one of acute infection, and if there be a fair proportion of epithelial cells present in the secretion under the microscope, I deem it a good case for the quick curative plan of treatment, etc." To-day, my larger experience causes me to modify the statement by saying, "and if there be a fair proportion of epithelial cells present (on which colonies of gonococci are seen)" we may expect success in the treatment. The result depends on the stage of the disease in which we attack it, and the amount of progress made by the infection may be estimated to a very great extent by the microscopical picture. The result of my personal study of many thousand smears, taken at all periods of the disease, has led me to the following conclusions:

During the period of incubation of the affection we find the normal pavement epithelium of the anterior portion of the urethra, and on the scales a large variety of bacteria consisting mostly of various sized bacilli, and a few varieties of cocci, mostly the

streptococcus and micrococcus ureæ, while we see only a few gonococci present, and these are sometimes difficult to make out.

In the prodromal stage a smear shows that all the nonspecific bacteria have disappeared, leaving the field entirely to the occupation of the gonococci in pure culture. But the formed epithelial scales are in great abundance, and the germs appear upon them in large colonies, while there are, comparatively speaking, few pus cells present, and in these considerable numbers of gonococci are seen, while some appear free.

As this stage progresses the number of pus cells increases, while that of the rhombic cells covered with the large colonies proportionately diminishes until the florid stage is reached, when the secretion consists almost entirely of pus cells containing large numbers of the specific microbes; the colonies have disappeared from the epithelial cells, and these latter are not of the same kind, but of the transitional variety, more rounded in outline, with a proportionately larger nucleus. At a still later period, many fields of the smear will show not a single epithelial cell, and the number of gonococci is apparently, though probably not really, decreased. It is foreign to our purpose to describe the microscopical appearances of the secretion in the further stages of the disease. These observations agree completely with those described by well-known observers.

The length of time, however, required for the development of these different stages, differs widely in different individuals, just as the period of incubation in which there are no symptoms has been known to last but one day, or has been as long as twenty days in two cases reported by good authority. So the length of time elapsed after the appearance of symptoms, whether it be one or five days, is no criterion of the stage of the disease, which must be judged entirely by the microscopical appearances presented by the smear.

In my opinion, these microscopical appearances show the extent to which the disease has progressed, and indicate to the surgeon the method of treatment to be employed.

The point of the matter lies in this. In the early period of the disease the gonococci lie entirely upon the outer layer of epithelial cells, and multiplying rapidly thereon, destroy the vitality of the cells, and cause them to loosen and exfoliate. This continues and the irritation of the microbes causes congestion, afflux of serum, and migration of leucocytes. This process is carried on until all the epithelial lining of the part attacked is shed, and the subepithelial tissue laid bare. At this juncture, the gonococci penetrate into the connective tissues, and the inflammatory period of the disease is well established. Just so long, then, as these epithelial cells, studded over with colonies of gonococci appear in the microscopical field, so long are the germs within reach of the germicide, and the case amenable to the quick curative plan of treatment.

The ideal plan of treatment is to remove the cause of the disease as early as possible, and this result can be accomplished when that cause is within reach. When the subepithelial tissues are invaded, it becomes impossible. In no disease in my experience, is the saying so true, *sublata causa, tollitur effectus*. As soon as the gonococcus ceases to appear, the discharge dries up and the mucous membrane of the urethra is restored in a very short time to its normal condition.

In speaking of this method of treatment to physicians, I have been met by the remark, "Oh, it is the old abortive plan." In answer to this, I would simply say that in both theory and practice it is entirely different, and I prefer to call it the quick curative plan. The old method was purely empirical, unsatisfactory, and untrustworthy. The new one is entirely scientific, perfectly controllable, theoretically perfect, and practically based on the well-founded facts of pathological anatomy, which modern methods have established. It was thought out and developed upon the lines of the pathogenesis of the disease.

An objection raised has been that by it there is a destruction of the epithelial coating of the urethra. This is by no means a valid objection, for such destruction is not at all harmful. It is of the very nature of epithelial covering to be quickly replaced, and in a very short time the surface is completely renewed. The disease itself rapidly destroys the epithelial layers, and does vastly more harm in many other ways. A moment's reflection will clearly present to the mind numerous analogous circumstances in other parts and organs of the body, where we deliberately destroy the epithelial covering, because it is not harmful to do so, and as before stated, epithelial structures are very rapidly regenerated.

A final objection is urged that few patients will present themselves early enough to the surgeon to have a quick curative method applied. This is true to a certain extent at the present time, but counts for naught against the plan itself, and is a fault that may justly be laid at the door of the profession. Patients have, heretofore, been led almost universally to believe that a quick cure can be rarely, if ever expected, and if it could, the method is bad and leads to injurious consequences. These beliefs are erroneous, and the sooner they are wiped out the better. Both profession and laity have become accustomed to the *laissez faire*, symptomatic plan of treatment, the most incipient cases even being allowed to go on to the florid stage, simply for the purpose of making a diagnosis. If patients were educated to the conviction that if they presented themselves at the first sign, they might expect a rapid termination of their complaint, there is not much doubt in my mind but that the vast majority, instead of a minority of patients, in private practice at least, would come early enough to get well quickly. Under any circumstances, let the microscope decide the question whether they can or cannot be quickly cured.

50 East Sixty-third Street.

## TREATMENT OF JOINT STIFFNESS BY MEANS OF GRADUAL RECTIFICATION COMBINED WITH MASSAGE.

By GUSTAF NORSTRÖM, M.D. (Stockholm),
NEW YORK.

In the year 1887 I published a monograph* on this subject, which at the time was received with great favor by the French medical press, and was furthermore regarded as an entirely original work. In this I attempted to present the different views that were entertained during late years on the treatment of false ankylosis and how the indications for treatment which were applicable to this had been understood. I also gave the history of the bloodless methods of restoring mobility, and described these as an introduction to the description of my own method. I reproduce in this article only the salient points of the above treatise. An abstract of the operative procedure applicable to the different

*Traitement des raideurs articulaires au moyen de la rectification forcée graduelle et du massage Paris, 1887, 137 pages.

articulations, as given in this monograph, follows. The method of overcoming the rigidity of limbs by manual force is by no means new. It has been practised for a very long time, but in the manner in which it has been performed the results have not generally been very satisfactory. As soon as reaction set in, the operator became frightened and stopped treatment altogether, or temporarily with the intention to resume it as soon as the irritation had subsided. The patient was then obliged to keep in bed for a longer period of time, antiphlogistics were applied, and when the proper moment had arrived to commence treatment anew, one was surprised to find that all that had been obtained so far was lost in the interval. On the other hand there were those who did not stop the rectification on account of the swelling, but continued the stretching and bending, although this often gave rise to almost unbearable pain to the patient.

Stiffness of the joint may be caused in three ways: By (1) traumatism, (2) rheumatism and gout, (3) chronic inflammation depending upon tuberculosis.*

1. The indications to be followed in *traumatic ankylosis* are readily found. The nature of the primary affection is known, and we may state that in cases which I have observed the results of the treatment have been excellent. The worst cases are those in which the false ankylosis has occurred after periarticular fractures. Those of the olecranon, for instance, are especially serious. Then the mobility of the articulation is often entirely or partially destroyed through the formation of an exuberant callus, which we cannot remove. The same may be produced in the knee, more rarely in the wrist.

Here the question arises whether ankylosis can be produced by immobilization alone. Menzel's experiments demonstrate that in some large animals like the dog, immobilization alone is sufficient to produce an alteration in the cartilages, which would lead to ankylosis if left alone. M. Reyher in 1873 tried some new experiments on this subject and obtained the same results; but he explains them differently from Menzel. According to the former, joints which primarily were not affected by disease and which became ankylosed through immobilization, became so because the synovial fringes which are formed in the neighborhood of the point of contact of the cartilages form adhesions amongst themselves. These are not the result of immobilization, but the result of the movements which lacerate them and cause irritations in the synovial membrane, or else they are called forth by the propagation of the inflammatory process to the neighboring parts.

These experiments and others seem to me to offer only a theoretical interest as we never notice such results in practice. It is possible that joints have become stiff, as for instance in treatment of fractures, through too prolonged immobilization. A true ankylosis, however, I have never observed. In all such cases I have found that repeated light flexion was sufficient to restore the normal condition. In no case was I obliged to resort to my method.

2. False ankylosis of *rheumatic* origin presents numerous varieties. They are all the more obstinate if the process is an old one, and if the attacks have been frequent. These are, however, not unfavorable cases for treatment. When there are no synechiæ or productions of new connective tissue, and the pathological changes are entirely confined to the periarticular fibrous tissue the tendons, and the fleshy parts of the muscles, rectification combined with massage gives results that could not be obtained either by forced extension or by forced flexion alone.

We now come to a series of cases of arthritis of *diathetic* origin occasionally leading to ankylosis. As regards false ankylosis due to gout, the best plan to follow would be to leave it alone. Any movement, no matter how slight, would not fail to stir up the primary disease and soon cause us to repent of not having abstained from such a procedure. The same applies, though to a less extent, to a false ankylosis following a hyperplastic granular synovitis. The information derived from pathological anatomy is not very encouraging. It amply justifies distrust and reserve. The fundamental rule ought to be to leave everything alone rather than augment by our interference the morbid process. When, however, the tuberculosis process has subsided and the patient presents himself with the customary contractions and ankylosis of various affected joints, the question arises: What are we to do? If ankylosis is complete our interference is useless and resection may be necessary.

When the ankylosis is not complete, neither the anatomical conditions nor the etiology furnish any contraindications to our intervention. In these cases of false ankylosis strength and perseverance will often yield unexpected results.

In a word, mechanical interference in the latter is useful only when the primary symptoms no longer exist and when the bacilli may be supposed to have disappeared. To advise noninterference in such cases, because of tuberculous origin, would be illogical, for, if bacteria are no longer present, a relapse or the dissemination of microorganisms is not possible. It may be difficult, however, to determine whether the bacilli are present or not. Among a great many good results, I remember having had local recurrences in two cases (in both of them the hip joint was involved), where I had every reason to believe that the process in question was under control.

Our method is simple. It consists of applying massage and manual reduction of the deformity, produced by the shrinking of the capsule as well as of the periarticular tissue.

Massage is used in various ways, both before and after rectification. Employed in the first for some time it softens the tissues, diminishes their tension and resistance, and gives them a certain flexibility; consequently it facilitates the maneuver employed. After extension or flexion massage in the shape of effleurage is performed for about ten minutes. Massage will then favor the absorption and not fail to remove the swelling often produced through our manipulations.* Besides, it is of real service in secondary atrophies. No procedure is better to stimulate or to regulate the nutrition of the muscles. Its physiological action explains this fact.

*Brisement forcé*, by stretching the retracted capsule or tearing the adhesions, often results in intra-

*Ankylosis produced by arthritis deformans we leave aside, as this is not amenable to the treatment under consideration.

*It is particularly after stretching the retracted muscles that the tumefaction develops to some high degree. But even this is of no consequence, for it will not persist if subsequent massage is faithfully performed. In the lower extremities, for instance, one observes when retractions of the semimembranous or semitendinous muscles or of the biceps exist, that at the beginning of the treatment a considerable tumefaction of the lower posterior part of the thigh takes place after every séance; later on the same phenomena will be produced at the upper part. All this is easily overcome by effleurage or slight true friction.

and periarticular hemorrhages, effusion, and swelling of an inflammatory character. This reaction may become still more pronounced if the joint was the seat of a swelling at the time of the interference. One can advantageously compare the disorders produced by the usual forced stretching to those resulting from a sprain. Absolute immobilization seems indicated. But is this, after all, the antiphlogistic measure par excellence? By no means. It does not facilitate the absorption of blood and liquids; on the contrary it favors the reproduction of stiffness and gives rise to reforming of the ankylosis, if there are lacerated bands, as these have a tendency to produce new adhesions.

It is then in a great many cases preferable to have recourse to a procedure which has demonstrated its utility and which does not contribute to the reproductions of adhesions.

I now come to the straightening of the limb. On the one hand we have people who wish to obtain immediate results; and on the other hand, timid ones who are frightened at the slightest crack and who expect the disappearance even of the pathological adhesions, I don't know how, without any lacerations. The sudden rectification (*brisement forcé*) is sometimes better than the gradual one, sometimes it is not. In cases where the adhesions are extensive or the bands are very numerous and short (*brides serrées*), I prefer the forced and rapid breaking up of the adhesions under anesthesia, to the gradual, progressive, and slowly effected correction of the deformity; and this all the more if the patient is sensitive, timid, and contracts his muscles very firmly at the slightest attempt at correction. But if I admit this, it is understood that this forcible breaking up of the ankylosis has always to be followed for some time by rational massage in order to combat the often enormous swelling (intra and extracapsular) which, under these circumstances, never fails to occur. In other cases, and particularly when the false ankylosis depends more upon a retraction of the capsule, a shortening of the ligaments as well as when muscular retraction is the cause of it, the gradual slow method is much to be preferred. The bands, when they are not too short nor too broad, do not offer a great resistance to the correction. As regards this category of cases, the shrunk capsule, etc., as well as the retracted muscles, certainly yield to the stretching under narcosis; but as soon as the operation is over they retract again to the same extent as before, and the joint remains as deformed as ever. You may apply a plaster of Paris dressing to combat this tendency, as it is usually done, but the pain during the first days, particularly if great resistance had to be overcome, is so great that it is scarcely bearable notwithstanding frequent injections of morphine. And when after some weeks, you remove the plaster of Paris there always remains a tendency to relapse or an ankylosis in extension has developed. Besides, the muscles in the neighborhood of the joint are often in a marked state of atrophy through the long immobilization in which the limb has been kept for weeks.

After each subsequent gradual rectification there is also, of course, more or less pain in and around the joint, proportional to the resistance that is to be overcome, but this pain disappears in a few minutes, as soon as the swelling produced by the maneuver has been removed through massage. This circumstance is due to the removal of the pressure of the liquid upon the nerve endings. A study of the clinical results of this method will tell how much we can expect of the various maneuvers. As I have already mentioned, in cases of marked resistance from swelling, preliminary massage in shape of frictions and also pétrissage ought to be employed for some time. The procedure is but slightly painful, the improvement is decided. The task is simplified, and we shall be in a better position to perform extension or forced flexion. If retractions of the capsule or of muscular origin prevail, then circumstances are less favorable, and correction must be commenced early. It is not necessary to wait until the inflammatory conditions have entirely subsided; in some arthropathies this temporization delays the beginning of the treatment and removes the chance of bringing about a cure in a relatively short time.

Deformities, retractions, and anomalies in the position and functions of a limb may find their cause in (1) the articulation or its vicinity, (2) in the muscles. We have observed joint lesions, thickenings and retractions of the capsule, formations of false ligaments, tendinous synovitis with adhesions of the tendons to their sheaths, myositis with a diminution of the extensibility of the muscles.

While massage of the joints is followed by a progressing amelioration and diminution of the pain and the patient consequently very soon plucks up courage, after the gradual rectification the joint is, during the whole treatment, in a condition of irritability, and is consequently more painful than at the moment when the treatment is started. It is, therefore, important to warn the patient, in order to prevent discouragement, which almost certainly would follow otherwise and before long.

In flexion or forced extension the resistances offered and the state of the osseous system must be taken into account. If we have to do with people in whom this is not properly developed, we must take care not to have the force act on too long levers, so as to prevent fractures.

In false ankylosis the contraindications are not numerous. I know only of senility, weakness, and extreme nervous impressibility. In the last cases, temporization is indispensable. It is useless to begin a treatment which must be interrupted. The invalid must be patient; he must get appropriate medication and his general condition must be built up and then it will always be time enough to begin.

And now let us consider the application of our procedure in the different joints.

*Ankylosis of the shoulder* is not an infrequent occurrence in spite of the normally great freedom of motion of that joint. The affection may, however, be concealed by the compensatory movement of the scapula, and the patient may not become aware of the ankylosis, even though advanced, until the scapula is fixed.* Active interference is nearly always necessary. Bonnet says we should proceed in the same way as in all other articulations; that is, by gentle and graduated movements or else by violent rupture of the adhesions.† The following is my method of procedure: The patient is placed in an armchair of which the back does not extend above his shoulder. I make him sit near the edge so that he may be able to move his

*As generally known, we are not able to lift the arm more than to the horizontal or, a little more, through an exclusive movement in the humeroscapular joint itself. Any more extensive movement in this direction is only obtained through the rotation of the scapula around an anteroposterior axis.

†Bonnet. Traité de thérapeutique des maladies articulaires

arm freely when he has to perform the movements. If, for instance, we have to deal with the left shoulder, we grasp hold of it and hold it steady, by very firm pressure,* at the same time with the other hand we seize the arm, above the elbow. Abduction is then made in the direction of the greatest resistance, that is to say, nearly always from below upwards and backwards. As soon as the resistance is less, I add movements of circumduction (*moulinet*), whose excursion I gradually augment.

If the resistance is considerable, or if quicker results are to be obtained, forced gradual abduction is preferable; this procedure allows of the display of more force. The patient sits on rather a high chair, while the physician stoops over in front of him on the affected side. The invalid leans with his elbow against the physician's shoulder. The operator then crosses both hands and places them on the diseased shoulder in order to fix the shoulderblade. He then rises, lifting up the patient's arm. This procedure, which is more powerful than the preceding one, is also more painful, and gives rise, of course, to more reaction on the joint. If the movements are getting more satisfactory, one may return to the first one.

During the last stage of the treatment, the patient ought himself to make active movements. Those of circumduction (*moulinet*), with or without dumb bells, seem to me to be the simplest and best. It has been claimed that these active movements can provoke inflammatory relapses, but I have never seen any.

Mrs. C., 42 years old, from Lyons, experienced ten years ago, after a stay at the seashore, violent pains in the right shoulder. The pains ceased after a few weeks. The same trouble reappeared without any appreciable cause the following winter, but were soon followed by marked improvement. Gradually she noticed inconvenience in moving her arm, and persistent but not very violent pain. Electricity (galvanization). The pain disappeared almost entirely, and the patient was able to use her arm enough to attend to her household without much difficulty. Until November, 1883, the result remained good. The patient even considered herself definitely cured. At this period a light attack. The movement of the arm became considerably limited, and she complained of great fatigue in it. It became impossible for her to lift anything heavy. The stiffness of the shoulder increased, so that she was unable to continue her work, and even to dress herself.

I saw this patient for the first time in March, 1885. The arm hung down and the forearm was in a position of half flexion. The deltoid and the supra and infraspinatus muscles were somewhat atrophied; there was slight pain on pressure in the scapulo-humeral joint. In immobilizing the shoulderblade the arm could not be moved more than sixty-five degrees from the thorax. When the shoulderblade was not immobilized, the arm could be lifted to a horizontal position, but the patient had difficulty in maintaining it, and could only do so for a short time. The arm was more easily brought forward, although it could not pass beyond the median line. Backward movement extended hardly as far as the great trochanter. She was unable to lift her hand up to her ear. The passive movement had a somewhat wider range. Massage of the joint and the periarticular muscles. The pain on pressure mentioned above disappeared. Forced gradual extension. During the first séances crackling and violent pain radiating into the arm and forearm were reproduced. After seven weeks all this had passed. At this period the articular stiffness was insignificant, and atrophy of the muscles had disappeared. When the shoulderblade was immobilized, she could raise her arm horizontally and maintain it for quite a long time in this position without getting fatigued. She could easily put her hand to the back of her neck, but not entirely as far as the other side of the neck.

*Ankylosis of the elbow.*—In ankylosis of the elbow, I firmly grasp the lower extremity of the arm with my left hand and the forearm a little above the wrist. I then impart gradual steady movements to it in order to increase extension by degrees until its angle exceeds the greatest preceding one. The arm must be kept extended two minutes or more, if the invalid can bear it. If the pain is too acute, recourse is had to effleurage, as usual.

We may also proceed in the following manner: The patient kneels down and puts his extended arm on a padded bench, or, if this is not possible, on an ordinary table; the physician stands at his side. We might also have him sit in an appropriate armchair or sofa so that the arm leans on a flat surface from the shoulder to the elbow. The maneuvers consist in gradually increasing the angle formed by the arm and the forearm, by using more or less force. In order to accomplish this, alternating movements of flexion and extension are necessary, and the patient ought to practise these as often as he can. It is useless to add that here as well as in the shoulder careful secondary massage is indicated.

In a variety more rarely met with, ankylosis in extension, the procedures are the same; the movements must, of course, be made in the opposite direction; if necessary, pronation and supination must be practised as well as flexion. Intelligent and constant participation on the part of the patient is required. The latter must try to contribute to the good result and make certain movements even if they should prove a little painful.

If we have to deal with ankylosis in flexion, I advise simultaneous gymnastic exercises; among others, suspension by the arms, if possible. To do this but a very simple apparatus is needed, consisting of a rope fastened to a ring or hook, which is fixed at a certain height.

Ankylosis in supination or pronation is rarely an isolated affection. If we have to deal with the former, the movements of extension and flexion must be executed with great precision, whilst pronation would be impossible. Rarely does an absolute integrity of the two movements of rotation present itself if the others are seriously impeded. Let us suppose that we desire to remedy the immobilization of the left elbow in supination We take hold of the elbow with the left hand in order to steady it; at the same time we grasp the forearm a little above the wrist, the thumb turned towards the palm, and communicate to the forearm several forced movements of pronation. If ankylosis is formed in pronation, the hands must be placed in the opposite direction.

*Ankylosis of the Wrist.*—Patients easily get accustomed to a diminution of mobility in the radiocarpal articulation; they can endure it better than that of the phalangeal or metacarpophalangeal articulations; stiffness of the wrist is less of a deformity than an inconvenience.

*This precaution is indicated in consequence of the mobility of the shoulder blade, which otherwise follows all the movements of the arm; this is also one of the reasons why this ankylosis is to a certain extent easily tolerated by the patients. Without preliminary fixation it would be impossible to bring about a proper rectification, to tear the adhesions, or to overcome the muscular or capsular retractions.

*Ankylosis of the Fingers (Toes).*—As I have just said, patients more easily become accustomed to ankylosis of the wrist than of the phalanges. This is always regarded as a deformity very difficult to put up with. The straightening is painful because the tendon sheaths, as well as the articulation, are nearly always affected. In all cases repeated interference, active and passive movements are of absolute necessity. I have often seen, when these joints had remained in flexion for a long time, a sort of epiphyseal osteophytes form at the points very remote from each other, and at the same time atrophy of the nearest parts, produced by pressure of these respective opposed surfaces. The same processes are also sometimes observed in the joint of the knee and particularly in that of the elbow. These cases are, of course, not susceptible to our treatment.

In manual reduction and straightening of immobilized fingers in a state of flexion, I employ, besides massage, a very simple apparatus consisting of a little board, pierced by rectangular holes through each of which passes the handle of an India-rubber strap, which is tightened as much as the patient can bear. The apparatus is used at least half an hour a day. During the first moments the pain is rather severe, but with a little good will on the part of the patient, he is soon able to endure it quite well.

All those who have studied the therapeutics of false ankylosis, particularly Bonnet,* Brodhurst, Nussbaum, insist on the difficulty of treating the coxofemoral articulation.

*Ankylosis of the Coxofemoral Articulation.*—Rigidity and muscular retractions are not to be neglected. If the thigh is flexed on the abdomen, which is most frequently the case, the retraction of the rectus femoris and of the psoas is a serious obstacle to rectification. Sometimes this is a more serious obstacle than those which exist in the joint. The patient lies on a properly padded table, so that the external surface of the leg reaches beyond it. The pelvis is firmly fixed by an assistant, the thigh is taken hold of above the knee, and we then proceed as in the other articulations. A great deal of strength is often necessary in order to overcome the resistance. The reaction is not great, unless we have to deal with the retraction of the rectus femoris muscle. Rectification proceeded with in accordance with the precautions indicated does not expose to any fractures.

Simultaneously with flexion adduction may exist but forced extension generally causes it to disappear. If at the end of treatment adduction persists, this is easily overcome by appropriate movements.

*Stiffness of the Knee Joint.*—The patient is seated on a firm bench properly constructed. Let us suppose that we have to remedy the right knee fixed in flexion, which is the most common correction we have to do. With the left hand we seize the thigh above the knee, whereas the right one grasps the leg above the tibiotarsal articulation, so that the lever may be as long as possible to enable us to use sufficient force. Successive movements are imparted to the leg, in order to form its maximum angle with the thigh. In every sitting this procedure is repeated four or five times, and each time we gain a little more. In this as well as in every other articulation we must take care not to abandon the limb directly after the séance, but to maintain it in extension or flexion for some time, one or two minutes or even longer if the patient can bear it. We must then never let the limb drop down, but gently bring it back to the first position; proceeding in this way one saves the patient a most disagreeable sensation. If the irritation is considerable, massage will soon quiet it. Effleurage and slight frictions give excellent results even in cases of very marked reaction.

Forced flexion is performed when the leg is immobilized in extension. It is seized simultaneously with the thigh as we have indicated. The movements are naturally performed in the opposite direction, and we endeavor to render the angle formed by the leg and thigh more acute.

In powerful and robust persons extension and flexion may be performed at the same sitting, especially if but a sight reaction follows each attempt. If the deformity is in flexion, forced extension is made, in the opposite case flexion. But more frequently we are obliged to separate these two maneuvers and make the extension and flexion of the joint at different times. I begin to work on the most pronounced deformity and on the one which will be more difficult to overcome. The same rule ought to be observed in articulations of the leg, the foot, the wrist, the fingers and toes.

When a deformity in flexion has for its cause a retraction of the posterior group of muscles in the thigh, this maneuver is no longer sufficient. In this case, as the leg is flexed, the forced extension must be performed on the shoulder. This procedure, which is very powerful, is more rarely applied than the other.

I apply it as follows: Let us suppose that we have to deal with a false ankylosis of the right knee with flexion of the leg on the thigh. The patient has to lie down on a sofa in such a way that the right half of the pelvis and the corresponding lower limb is a little nearer the edge; the physician himself stands on the right side of the patient and leans with his knee flexed against the edge of the sofa, in such a way that the diseased leg rests by its posterior surface on the physician's right shoulder. The doctor grasps the limb with both hands above the knee, then rises slowly, still holding the ankylosed knee; this maneuver is repeated four or five times at every séance. It is indispensable to immobilize the other leg; without this precaution the patient will move this side, the pelvis will be slightly displaced—the fixation of the thigh not being a complete one—and only an insufficient rectification is obtained.

M. S., 38 years old, a baker. On August, 1882, in lifting a bag of flour he experienced a violent pain in the left gluteal region. The patient was nevertheless able to attend to his business the following days; but the pain reappeared with its former intensity as soon as he was obliged to make an effort to work. He resorted to methodical treatment only in March, 1883. Several vesicatories; the pain only increased; hydrotherapy did not succeed any better. The leg on the affected side began to atrophy; violent pain in the right side of the knee, tumefaction in the region of the right buttock; walking difficult. A surgeon of Bordeaux diagnosticated a muscular rupture in the lumbar region and prescribed the waters of Barèges. The patient stayed there a month, but without much benefit, and at the end of the season the leg had even shortened considerably. Disheartened, he applied to bone-setters. These resorted to violent extension. The application of these procedures was followed by an apparent curvature of the body on the affected side, walking became impossible; the patient could not take a step, and not even sit down without help. His general state of health suffered extremely under

*Bonnet, loco cit.

these circumstances. I saw the patient for the first time in March, 1884. The leg presented marked flexion at the knee and formed an angle of 135 with the thigh. This was flabby and thin. It could not be extended beyond the limit mentioned. Flexion almost normal. Forced extention of the contracture of the leg. This contracture was of a muscular nature and organic; it was rather a shrinking (retraction) of muscular elements, and had its seat in the muscles in the posterior region of the thigh. Pain and tumefaction followed almost immediately after traction in the lower part of the thigh and in the neighborhood of the knee. They were soon alleviated by massage. Thanks to this the pain and swelling were so much relieved after only a sitting (a quarter of an hour) that the patient was able to walk a little. After eight or ten sittings there was no cracking and no tumefaction after the manipulations. Very slight reaction in the knee joint. A fortnight after the beginning of the treatment the patient was able to take rather long walks. After six weeks he was quite cured and walked as well as before the injury. The limping was almost imperceptible. There remained but slight inclination of the body to the left. The atrophy of the muscles of the thigh had disappeared, thanks to energetic massage; no traces of the lumbar myositis remained. Some months later I received a very explicit letter from this patient; the result obtained persisted. There remained only a very slight inclination of the body to the left.

I have treated several cases of stiffness of the tibiotarsal joint with equal success. The maneuvers are very simple and do not require any special description.

122 East Thirty-fourth Street.

## FOUR CASES OF ESSENTIAL ANEMIA AND THEIR DIAGNOSTIC DIFFERENTIATION.*

By WILLSON O. BRIDGES, M.D.
OMAHA, NEBRASKA.

*Acute Lymphatic Leukemia.*—J. C. E., male, was referred to me for examination April, 1904. He is a resident of Nebraska, American, aged 40 years, blacksmith, married, and father of eight children. He never drank to excess, but had used a pound of chewing tobacco per week for fifteen years. His father is well at 76. Mother died at 55 of some liver and stomach trouble. One sister died at 26, two days after confinement, with dropsy and coma; one brother died at 33 from contracting an infection from a glanders horse.

He had typhoid fever at 14 years of age without complications or sequel. Occasional burning sensation in the epigastrium, and eructations had occurred for many years after eating greasy food. In April, 1903, he had la grippe, lasting two weeks, followed by dry catarrh of the middle ear, which was relieved by treatment. In December, 1903, he contracted a severe cold on exposure to a full day's wetting, which lasted four or five days, terminating in complete recovery. Early in March, 1904, a dull, aching pain across lower posterior chest developed, more intense at night, which had extended to lumbar region, and was persistent to the time of examination. Three weeks previously, while duck hunting, he noticed that he was short of breath on exertion and had grown steadily worse. Any physical effort had been attended by increasing fatigue for four weeks, and he had lost ten pounds in weight in that time. He had noticed also dizziness and faintness on exertion. There had been no edema, but for two weeks palpitation was evident on making any physical effort. No diarrhea or vomiting or hemorrhage of any kind had occurred. He had felt slight fever at times recently. On admission to the hospital, April 6, 1904, he was extremely pale, the ears translucent, mucous membrane of the lips and mouth was colorless. There was no icterus or apparent emaciation. There was no complaint of pain, but only extreme fatigue on making any physical effort. The temperature was 97.2 by the mouth, pulse 76, soft and compressible. Enlarged glands in the inguinal, axillary, and the post cervical regions of both sides were pronounced, and the inguinal involvement only had been observed by the patient for several months preceding. The glands were distinctly movable, slightly tender, and separate. The spleen and liver were palpable on deep inspiration, but not much enlarged. A tumor the size of a goose egg could be palpated just above the umbilicus, slightly tender and freely movable. This was not affected materially by inflating the stomach and chemical examination of the stomach contents after a test meal revealed decreased hydrochloric acid and no lactic acid. There was no evidence of heart lesion, though the systolic sound was not strong and a soft, anemic murmur was present. The urinary findings were negative. Two blood examinations were made by Dr. Truelson on different dates, nearly identical in results as follows: Hemoglobin, 23; red cells, 1,232,000; white cells, 385,000; megalocytes numerous, microcytes present, normoblasts present. Differential count of white cells (percentages): Small lymphocytes, 88; large lymphocytes, 8; polynuclears, 3; eosinophiles, 1.

The patient insisted on returning home after being under observation only four days. Later information received from a physician, who had been called just before death, stated that he rapidly became worse, the abdominal tumor grew larger, he had much pain, became slightly icteric, and died in coma June 25, two and one-half months after my examination, and within five months after the first symptom described. Unfortunately, no autopsy was held. In this case the tumor in the abdomen referred to gastro colic omentum. It may have been a gastric was thought to be a mass of enlarged glands in the carcinoma, but the general lymphatic enlargement with the blood picture stamped the case as one of leukemia, and the diagnosis was concurred in at the time by members of the Douglas County Society, before whom the patient was exhibited.

*Spleno-Myelogenous Leukemia.*—A. M. T., American, male, aged 40, railroad engineer, married, was seen in consultation in May, 1904. His father died at 36; cause unknown. Mother is living, at 70. Two brothers died in infancy. One maternal aunt died of cancer of the breast. He had measles and mumps in early childhood; intermittent fever at 11, lasting thirty-five days. At 13 he had right hemiplegia with aphasia, from which he fully recovered in two years. At 18 he contracted a venereal sore, which was said to be syphilitic. It disappeared after five weeks' treatment, and was not followed by secondary symptoms. At 33 he was laid up three weeks, after an injury to the right shoulder. He was then well to about three months previous to my examination, when he had pain and discomfort through the lower left chest posteriorly, aggravated by exercise. He then noticed commencing loss of strength, and a feeling of fullness in the left hypochondrium enabled him to detect a tumor ex-

*Read before the Missouri Valley Medical Society, August 24, 1905.

tending beyond the rib margin. There had been slight epistaxis during the past two weeks, and some headache. He had lost four pounds in weight in six months. He presented for examination May 10, 1904. He was pale, in good flesh, pulse 90, soft and rather feeble, temperature by mouth 99.4°. The heart apex was displaced slightly to the left and upwards. No murmurs were detected. The abdomen was very prominent, the result of an enlarged spleen which extended slightly to the right of the median line at the umbilicus and nearly to the left anterior iliac spine. It was hard, somewhat tender, and the notch could be plainly outlined. A few slightly enlarged glands were felt in either groin; none elsewhere. The urine passed the following twenty-four hours measured two quarts, S. G. 1022. Urea three per cent., albumin absent, numerous hyaline, and a few granular casts were found. Two blood counts were made at forty-eight hours' interval by Dr. Truelson of the Medical Department of the University, with only a slight variation, and resulted as follows: Red cells, 3,244,000; white cells, 295,000; hemoglobin (Dare), 48 per cent. Differential count (percentages): Polynuclears, 55; small lymphocytes, 2; large lymphocytes, 4; transitionals, 4; eosinophiles, 1; myelocytes, 34; megalocytes, microcytes, and normob'asts present.

The diagnosis of splenic leukemia was made and arsenic advised in increasing doses. No results in the size of the spleen being noticeable after two months, the *x*-ray treatment was advised, which was carried out by Dr. Andrews, with the result, after three months, of a reduction in the splenic enlargement of fully one-half, and a blood count on November 28, as follows: Red cells, 3,512,000; white cells, 14,200; hemoglobin, 60 per cent. Differential count (percentages): Polynuclears, 62; small lymphocytes, 18; large lymphocytes, 7; eosinophiles, 1; myelocytes, 12; normoblasts present. The patient left greatly improved, and he was desirous of returning to his occupation. On June 15, three months after a discontinuance of the *x*-ray treatment, he was not so well, and the spleen had enlarged again considerably. No count was made.

*Splenic Anemia with Atrophic Cirrhosis of the Liver.*—J. F. M., American, aged 65, married, retired farmer, was referred to me in the autumn of 1904. His father died at 42, after two months' illness; cause unknown. Mother died at 70 of goitre. One sister died at 40, after confinement. One brother died at 16, of typhoid fever. He had intermittent fever at intervals from the ages of 18 to 21 while residing in a malarial district. This later recurred with bilious attacks frequently during his service in the War of the Rebellion. After the war he resided in Alabama, where it again recurred. He later moved North, where he was again afflicted for two seasons. In 1885 he vomited over a pint of blood, without other symptoms, and with no known cause, and again three weeks before presenting for examination. He was then in fair health until 1896, when he first observed shortness of breath, followed by some pain in the chest, which troubled him for the ensuing three years, and recurred at intervals since. Dyspnea had grown much worse lately. Several times he has passed blood from the bowels, said to have been from piles. During the past eight years he has gradually lost flesh and strength, and there has been increasing discomfort and a full feeling about the abdomen and chest. For four or five years he has been very pale. Latterly fever at times, indigestion and swollen feet have been noticeable. He states that for four or five years he has known of his spleen being much enlarged. He presented himself for examination September 26, 1904. He was very pale and slightly icteric. The abdomen was prominent and edema of the lower extremities was evident. The heart apex was displaced to the left and a systolic murmur heard over the entire precordium and in the neck vessels. There was fluid in the abdomen, the liver dullness was diminished, and the spleen was enormous, reaching past the umbilicus and to the crest of the ilium. The organ was hard, tender, and the outline, with the notch distinct, could be readily made out with the patient lying on the right side, notwithstanding a considerable amount of fluid in the abdomen. The pulse was 116, irregular and soft. There was slight fever. A blood count, made by Dr. Goetz, showed: Red cells, 3,900,000; white cells, 3,400; hemoglobin, 34 per cent.; tendency to poikilocytosis. Differential white count (percentages): Polynuclears, 66; small lymphocytes, 28; large lymphocytes, 5; eosinophiles, 1. A second examination, made three days later by Dr. Truelson, indicated: Red cells, 3,088,000; white cells, 1,100; hemoglobin, 28 per cent. Differential count (percentages): Polynuclears, 33; small lymphocytes, 63; large lymphocytes, 4; poikilocytes very marked; megalocytes present; microcytes numerous. The patient was put upon iron, arsenic, and strychnine, with cardiac stimulants and diuretics, with instructions for absolute rest. He insisted on returning to his home in Iowa, where, I have recently learned, he died about two months after my examination. The diagnosis of splenic anemia in this case was based largely on the enormous size of the spleen, which had been known to be very large for several years, with the blood findings indicating a chlorotic type with leucopenia. The associated apparent cirrhosis of the liver would correspond with the cases described by Banti, and which some authors have endeavored to show present conditions not true to simple splenic anemia, and hence designated them as cases of Banti's disease. True, in this case there was an old heart lesion, as shown by a mitral regurgitation and enlargement of the heart, which, with the interference in the portal circulation by an atrophied liver, might account for a considerable enlargement of the spleen, due to passive congestion; but the slight degree of edema of the legs and the moderate ascites with the clinical history led me to believe that there must have been a prior lesion of the spleen, which I admit was intensified by the hepatic and cardiac complication. It is unfortunate that an autopsy could not have been obtained, as the case might have thrown some light on a subject about which there is much diversity of opinion expressed in recent literature regarding the existence of so-called splenic anemia as an essential anemia.

*Pernicious Anemia.*—R. B., American, male, aged 45, married, janitor. His father died at 79 of senility. Mother at 52; cause unknown. Two brothers died in infancy. He has lived in Nebraska since childhood. He had chills and fever at 10, lasting nearly one year; at 35 was laid up for one month from overwork. He was then well until the fall of 1904, when he noticed commencing fatigue after exertion. He was then said to look pale. He grew gradually worse through the winter, until recently he was so constantly tired and became so weak that he was obliged to give up even light work. For the past three weeks he has had two loose bowel movements of normal color daily. He had lost only about ten pounds in weight. There had been some palpitation and short breath on attempted exertion. He had no stomach symptoms whatever; nor had there been hemorrhages of any kind. He presented for examination April 24, 1905. He was extremely pale, with a slight icteroid color of the skin, and the ocular sclera was pearly in hue. The mucous

membrane of the lips and gums was colorless; the ears were bloodless. There was no apparent emaciation, but the muscles were flabby and the skin relaxed. The spleen could be barely palpated. The liver dullness was normal, and there was no tenderness or abnormality about the abdomen. The heart area was normal, but a faint systolic murmur could be detected over the base. The pulse was 102, soft and weak, temperature by mouth 99.5, urinary examination was negative. A test meal evacuated from the stomach after taken one hour showed no response to the hydrochloric reagent, neither was there lactic acid. Inspection of the bowel movements failed to reveal anything abnormal as to color or composition. A blood examination on two different dates by Drs. Truelson and Goetz resulted, with but little variation, as follows: Hemoglobin, 27 per cent.; red cells, 1,296,000; white cells, 5,000. Differential count (percentages): Polynuclears, 63; small lymphocytes, 32; large lymphocytes, 4; myelocytes, 1; megalocytes and microcytes numerous; poikilocytes well marked. The subsequent history of this case to date with further corresponding blood findings, notwithstanding the administration of iron and arsenic in increasing doses, with a system of forced feeding, which included bone marrow in considerable quantity, corroborated the original diagnosis of pernicious anemia, which was based on the absence of any cause for a relative anemia, the peculiar hue of the skin and the mucous membranes, the symptoms of progressive weakness, and the blood findings.

In considering the differential diagnosis of the essential anemias, it is assumed in the individual case, every possible cause of a relative or secondary anemia should be eliminated; for while it is acknowledged that the blood picture between any relative, and some of the primary anemias, is not always so different as to determine the diagnosis by itself, yet this is true for the most part. Also between the different forms of the primary anemias it is assumed that the clinical history and the physical examination of the patient are of great importance in their differential diagnosis, and it is only when taken into consideration with the blood findings that we may feel reasonably certain as to our conclusions. We know that in splenic leukemia there is great enlargement of the spleen, with occasional slight involvement of the lymphatic glands. In lymphatic leukemia there is general enlargement of the lymphatic glands, with only slight involvement of the spleen. In splenic anemia the spleen is usually enormous. In pernicious anemia the spleen is only slightly larger than the normal, if at all. In Hodgkins' disease there is general lymphatic enlargement, with no change in the spleen. In all of these anemias there is marked pallor, great weakness, bodily and mental torpor, dyspnea on exertion, palpitation, cold extremities, a blood examination one might confound splenic anemia with splenic leukemia and lymphatic leukemia with Hodgkins' disease, and pernicious anemia, with indigestion, and constipation or diarrhea, and possibly hemorrhages, dating back for an uncertain period, so slowly do the symptoms develop, and but for chlorosis or a secondary anemia. My case of splenic anemia was sent to me, with a diagnosis of leukemia, and the case of splenic leukemia, reported above, was pronounced carcinoma and syphilis of the spleen by two different men, respectively. Before the blood examination was made in the case of pernicious anemia (my own) I was inclined to suspect carcinoma of the stomach. I have arranged the following table, which indicates the comparison of blood findings found in the cases herein reported, and which represented the usual relation as laid down in most text-books:

| | Hemoglobin Index | Number of Red Cells | Poikilocytes, Macrocytes, Microcytes | Number of White Cells | Polynuclears Percentage | Large Mononuclear Percentage | Small Mononuclear Percentage | Myelocytes Percentage |
|---|---|---|---|---|---|---|---|---|
| Lymphatic Leukemia | 1 | 1,232,000 | | 385,000 | 3% | 8% | 88% | |
| Splenic Leukemia | 1 | 3,244,000 | | 205,000 | 55% | 4% | 37% | 34% |
| Splenic Anemia | 1 | 3,900,000 | | 3,400 | 66% | 5% | 28% | |
| Pernicious Anemia | 1 | 1,296,000 | Present | 5,000 | 63% | 4% | 32% | 1% |

That variations from these comparisons may and do occur is sufficient ground for not relying on the blood findings alone for a diagnosis, and, as stated above, they are of value only when considered with the clinical history and the physical examination of the case. For instance, Strauss and Rohnstein reported two cases of pernicious anemia in which the enumeration of red cells were over 4,000,000, and yet one of the patients presented with such a degree of weakness as to incapacitate him. Since this paper was commenced I saw a case of splenic leukemia with Dr. J. E. Summers, in which there was enormous enlargement of the spleen without any involvement of the lymphatic glands whatever, and yet the differential counts as made by Dr. Lavender were classically those of lymphatic leukemia as follows: White cells, 152,000; small mononuclears, 86 per cent.; large mononuclears, 10 per cent.; polynuclears, 4 per cent.; myelocytes, 8 per cent.; eosinophiles, 20 per cent.

## FURTHER REPORT OF A CASE OF PRIMARY LUPUS VULGARIS OF THE OROPHARYNX AND NASOPHARYNX, TREATED BY X-RAYS.*

By H. S. BIRKETT, M.D.,
MONTREAL.

PROFESSOR OF LARYNGOLOGY AND RHINOLOGY, MCGILL UNIVERSITY MONTREAL; LARYNGOLOGIST AND RHINOLOGIST ROYAL VICTORIA HOSPITAL.

At the meeting of this association a year ago, I had the honor of presenting a report of a case of primary lupus vulgaris of the oropharynx and nasopharynx, treated by *x*-rays (*Transaction of the American Laryngological Association* for 1904, and the Medical Record, December 24, 1904); some of the members kindly requested that I should report further upon the progress of this case under the treatment then adopted, and I have much pleasure in complying with their wish on the present occasion.

I last saw this patient in May, 1904. At that time the lesions which had shown themselves in the nose, oropharynx and nasopharynx had entirely disappeared. It was not until December of the same year that the patient again presented himself at the Nose and Throat Outpatients' Department of the Royal Victoria Hospital. He came, not that there were any symptoms which needed attention, but merely to report. Examination of the sites of the former lesions, namely the oropharynx, the nasopharynx, and the cartilaginous portion of the septum, showed the local conditions to have remained absolutely healed, and the only indications of their former presence were fine linear cicatrices.

Upon examination of the larynx, the epiglottis was noticed to be swollen and infiltrated, and its surface studded with minute infiltrations, pin-head

*Read at the Twenty-seventh Annual Congress of the American Laryngological Association, Atlantic City, N. J., June, 1905.

in size. At the extreme periphery of the epiglottis these infiltrations stood out individually, but proceeding from this point to the body of the epiglottis they gradually became smaller, and finally merged into the smooth surface of the mucous membrane. The epiglottis was so swollen and enlarged that when lying in a quiescent state, it came in contact with a point directly opposing the posterior wall of the pharynx. In this portion of the pharynx a small ulcer was noticed, in size about 7 mm. wide and 5 mm. broad, and in outline almost circular, the edges of which were infiltrated with small, round, nodular thickenings, in color slightly paler than the surrounding mucous membrane, and corresponding exactly in color with those on the edge of the epiglottis.

The subjective symptoms were entirely negative and the patient was unaware of the newly existing conditions in his throat. There was no question from the appearance of the local trouble that we had the same pathological process as that which existed in the upper portions of the respiratory tract, making itself known in another region.

The application of the *x*-rays was at once begun. They were applied externally through the tissues in the front of the neck corresponding to the parts invaded within. The same precautions were observed in treating this new area of infection as were carired out when applying the treatment to the previously invaded region. The applications were made four times a week, the duration of the application being increased from ten minutes to twenty minutes. This treatment has resulted in definite cicatrization of the right half of the epiglottis. This is proceeding satisfactorily towards the remainder of the epiglottis, and the ulceration on the posterior wall of the pharynx has been so far diminished in size that it measures but 3 x 2 mm.

In the report of this case presented last year, I made a brief note of a patient who was suffering from lupus of the nose which, before coming under observation, had destroyed the greater portion of the nose, and had involved the epiglottis in a similar process. *X*-ray treatment was instituted in this case at that time. I have had the opportunity of seeing this patient quite recently, and am glad to be able to report a complete disappearance of the lesion involving the epiglottis with the result, however, that it has left the epiglottis destroyed to half of its extent.

Whilst I do not care to make definite statements regarding the usefulness of this form of treatment for lupus of the mucous membrane of the respiratory tract, yet I think one may look upon the results obtained in these two cases, with a fair amount of justice, as sufficient to warrant its trial in the place of so many other therapeutic measures, the results of which have been anything but satisfactory.

---

## ACUTE PANCREATITIS.

By JOHN G. SHELDON, M.D.,

TELLURIDE, COLORADO.

This article is not written with the idea of adding to the knowledge of pancreatic disease, but for the purpose of calling attention to certain considerations regarding the disease that are at the present time unsettled, and which are so often unmentioned by those who contribute to the knowledge of diseases of the pancreas. The physicians who reside distant from the centers of medical education are many times at a loss to know the opinions of those who are best qualified to give advice on certain important, but unsettled, considerations in rare and obscure conditions. Many articles leave unmentioned that which we, as "Country Doctors," wish to have discussed.

There are a few considerations that suggest themselves in dealing with acute pancreatitis that may be of importance, but are passed over hurriedly, or not touched upon at all, by many who give advice on pancreatic diseases.

1. Cambridge and Robson have stated that the finding of glycerin in the urine—that is recognized by practically the tests for glycerose—is characteristic of pancreatic disease. Further reports on this observation are difficult to obtain. Carl Beck, in an article published in the *Medical News* of September 9, 1905, states that "in summing up, it becomes evident that there is not one sign which is absolutely pathognomonic for pancreatitis." He does not mention the significance of glycerin in the urine, and we are uncertain that he has disproved the contentions of Cammidge and Robson.

2. There seems to be a difference of opinion regarding the nature of acute pancreatitis in its beginning stages. Theoretically and experimentally, as well as clinically, there is considerable evidence in support of the contention that acute pancreatitis, at its beginning, is dependent upon mechanical conditions, and that the primary changes in the pancreas are entirely chemical, and not the result of bacterial invasion. The experimental pancreatitis produced by Opie, Pearse, Flexner, and Hewlett, suggests that acute pancreatitis, in all stages and all degrees of severity, can and does occur as an aseptic process. The work of Pawlow, who observed that the bile increases the efficiency of the fat-splitting ferment of the pancreas, also supports the mechanical theory of pancreatitis. Hlava has shown clinically that the exudate in a case of acute hemorrhagic pancreatitis contained no microorganisms. While there is support for the belief that infection in acute pancreatitis is to be regarded as a secondary complication, and not as the primary factor in producing the disease, Dr. Beck requests us to realize "that acute pancreatitis is virtually an infectious process not unlike acute appendicitis."

3. The reports of cases of acute pancreatitis are as a rule, quite indefinite regarding the condition of the gall-bladder. I have found the gall-bladder distended and very tense in three out of four cases of acute pancreatitis observed at operation or autopsy. While the condition of the gall-bladder may be of little value in determining the nature of, or the best method for treating pancreatitis, it may be that a tense gall-bladder would favor the mechanical theory of the disease, and suggest that early cholecystostomy might meet the pathological indication in these cases. I have done a cholecystostomy in a supposed case of acute pancreatitis twelve hours after the onset of the symptoms. The gall-bladder was tense and contained dark tarry material that was free from microorganisms. Prompt improvement followed the drainage of the gall-bladder, and the recovery was complete and apparently permanent.

Beck suggests that cholecystostomy may often be expected to relieve acute pancreatitis. While at the present time drainage of the gall-bladder cannot be looked upon as the accepted early treatment of acute pancreatitis, it is possible that cholecystostomy may be the most efficient of operations in dealing with this disease in the very early stages.

---

**Ward Rats.**—At Acton, England, recently it was stated that the nurses at the public hospital were afraid to enter some of the rooms on account of the rats and that the rodents terrified the patients at night by sitting on their beds. The matter was referred to a committee "with power to act."

MEDICAL RECORD.

New York, November 4, 1905.

## THE ARMY CANTEEN.

With each recurring autumn, when the annual reports of the Department Commanders of the Army are made, testimony accumulates in support of the moral value of the post exchange, or canteen, as it is usually called. It is now nearly five years since the efforts of the misguided ladies, who do so much to promote vice through their endeavor to make virtue compulsory, succeeded in bringing about an act of Congress closing the canteens. The policy of abolition has, therefore, prevailed for a sufficiently long period of time to warrant the passing of judgment upon it as a moral force in the army, and the unanimous judgment of those best fitted by observation and experience to express an opinion, is that the closing of the post exchanges has had the most deplorable results. Drunkenness, gambling, sexual immorality, with the resultant venereal disease, infractions of discipline, desertions, and insanity, have all increased since the sale of beer and light wines in the post exchanges was forbidden by law, and the causal relation of the closure of the canteen to the loss of moral tone among the soldiers is undeniable. The testimony of every division and department commander in the army is all one way.

In his report just published, Gen. Grant says that fully 75 per cent. of the 12,042 summary court-martial trials of enlisted men in the Department of the East, during the year, were due to the use of bad liquor, dispensed to our soldiers by persons who conduct dens of vice in the vicinity of military posts. These depraved creatures use every device in their power to induce the soldiers to patronize their places, where those who yield to temptations are frequently drugged and robbed. Gen. Wint, commanding the Department of the Missouri, speaking of the desertions, which furnish about one-third of the general court-martial trials, says that a great majority of them trace their history to drunkenness, induced by the environment of the low dives and vicious gambling and drinking resorts infesting the neighborhood of most of the posts. The evil is even worse in the Philippines, where Gen. Carter, of the Department of the Visayas, has shown most clearly that the hundreds of soldiers who are being brought home insane from the islands are the victims of the abolition of the canteen. Instead of taking pure beer in moderation at the post exchange, they are led by the abolition of the canteen to make use of the poisonous native drinks. Another evil of the abolition of the canteen is that the soldier is cheated and robbed of his earnings in the gambling dens, groggeries, and brothels, which have sprung up around all the army posts of any size. The Paymaster-General of the army reported last year that since the abolishment of the canteen the amount of money deposited with the paymaster's office by the enlisted men, had decreased by nearly two millions dollars.

The Seaman prize of the Association of Military Surgeons, awarded annually for the best essay on "The Prevention of Disease in the Army and the Best Method of Accomplishing that Result," was given this year to Major Jefferson Randolph Kean, Surgeon, U. S. A., for a paper in which he made a strong plea for the reestablishment of the canteen at army posts. He showed by statistics that since the canteen was abolished all kinds of diseases traceable to dissipation have increased in the regular army. The reason, he said, is that low groggeries have sprung up around army posts where soldiers drink to excess and then fall victims to disease.

In contrast to these pictures, all exactly alike, of the fearful evils which have followed the abolition of the canteen feature of the post exchange, is the positive testimony of the good the canteen did when it was permitted to exist. This is found in the statement of Gen. Jesse M. Lee, in his annual report, in which he says that "a well-regulated canteen, where beer and light wines may be sold, conserves discipline, controls and decreases drunkenness and disorders, lessens absenteeism, and to that extent tends to reduce desertion."

The good, but awfully mistaken women, who have brought this calamity upon our soldiers, are unable to deny the damning facts which the generals of the army bring forward each year in their official reports, but still attempt to justify their action by the wicked old shibboleth, "no compromise with vice." Better, they say, that thousands of young men in the army should be ruined, their souls debauched, and their bodies diseased, than that a Christian State should sanction the sale of beer and tobacco. One of their pet arguments is that the soldier should be forbidden to drink. Railways and other great corporations, they say, have made a rule that their employees shall be total abstainers, and the army, they think, can do the same. They forget that among the employees of corporations only those who hold positions of great responsibility, such as the switchmen, train dispatchers, and locomotive engineers, are compelled to abstain from the use of alcohol, and also that men seek employment on the railways and in the various industrial occupations, but that the army seeks the recruit. If total abstinence was demanded of the soldier there would have to be some other system than recruiting devised to keep up the strength of the army.

It is practically certain that a bill will be introduced in Congress this coming winter to restore the canteen, and there is every hope that it will pass, despite the opposition of the curious alliance of the whiskey dealers and the ladies of the W. C. T. U. These are the only enemies of the enlisted men in the army, so far as we know, while on the side of morality are all the officers of the line, the chaplains, and the members of the medical corps, the Women's Army and Navy League, and all who believe in persuasion rather than compulsion as an efficient moral force.

## INOPERABLE CARCINOMA OF THE UTERUS.

The combat against cancer of the uterus occupies a prominent position in the foreground of gynecological endeavor, but in spite of all the study and attention which the subject has received and the many therapeutic efforts which have been made to overcome the dread disease, we must still admit that whatever knowledge we possess of the nature and extension of the affection is lamentably insufficient for our purposes. But although the search for the solution of the problem has not been crowned with complete success, further efforts should not be abandoned, for the good results obtained with operative measures in many cases, show that the hope of cure is not an impossible one, and there is ground for the belief that any cancerous particles which may have remained after what must necessarily be an incomplete operation, can undergo a process of degeneration which renders them innocuous. Surgery has been favored with an increasing measure of success in this condition, as the technique has been perfected and methods for the early recognition of the growth have become more generally known. But the hope which is held out to that class of patients who can be operated upon at an early period, is entirely lacking in the prognosis which is delivered to those in advanced stages who are declared "inoperable," and who must drag out their increasingly miserable existence, a burden to themselves and those about them. What to do for these afflicted women has remained a problem of gynecological practice. After being abandoned for a time, the idea is now again gaining ground that some palliative operation should be resorted to even in advanced cases, ordinarily considered inoperable. This aspect of the question is exhaustively discussed in a recent article by Chrobak, of Vienna (*Wiener klinische Wochenschift*, No. 38, 1905), in which he deplores the treatment usually accorded to the latter class of patients and combats the rather prevalent idea that palliative measures in an advanced case are futile, and that a sufficient quantity of morphine will alone afford the desired relief to the sufferer. It may be said with a great deal of truth, perhaps, that the latter opinion is often governed by the personal convenience of the physician. In advocating such palliative measures as curettage and the application of caustics to the interior of the uterus, repeated if necessary, together with appropriate local and constitutional treatment, Chrobak in no way deprecates the radical operation; but he asserts that no comparison as to results can be drawn between series of cases treated by one or the other measure, and furthermore it is not fair to compare the cases treated at the present day by palliative means with those of a former generation, as many of the latter would undoubtedly have been subjected to radical operation with our present day knowledge of the subject. The suggestions made by Chrobak may well be studied and followed, for such endeavors to alleviate the pangs of the inevitably fatal termination of these "inoperable" cases, will redound to the credit of the physician who puts them into execution, and will also quiet his conscience in having provided all that is possible for the euthanasia of the unfortunate woman.

### The Significance of Balantidium Coli.

There still seems to exist at the present day considerable obscurity regarding the pathogenic importance of the *Balantidium coli* in man, and if mentioned at all in recent text books, it is usually referred to as an accidental invader in certain cases of diarrhea or dysentery, and its injurious influence is doubted. Later investigations make it appear probable, however, that this parasite is capable of causing a specific diarrhea, not infrequently of a serious nature. R. P. Strong, director of the Biological Laboratory in Manila (Bulletin No. 26, Bureau of Government Laboratories, Manila), has collected 117 cases from the literature, and the study of these should afford material for more definite ideas regarding this infusorium than we have hitherto been favored with. In his own case (a soldier inmate of the hospital in Manila, who died from the effects of the disease), a very careful clinical history and pathological examination were obtained, and taking the results together with what is already known of the condition, the author seems quite within bounds in assuming that the diarrhea which is associated with the presence of *Balantidium coli* in the stools, is due to this parasite. Moreover, the diarrhea will be found to persist until treatment is directed immediately against the organism. An interesting point which may explain the mode of infection is the fact that 25 per cent. of the patients in the above list gave a history of having come in contact with pigs or of having eaten the raw flesh of the latter in fresh sausages. In addition to this, the parasite has often been found with the hog as a host. The large intestine in patients who had succumbed to the disease, showed at autopsy ulcerative processes similar to those of amebic dysentery, and more careful histological study of some of the cases has also disclosed an invasion of the coats and vessels of the colon. Whether this protozoan is capable of producing a primary erosion of the walls of the gut has not as yet been conclusively demonstrated. If an erosion is present from another cause, however, the parasite is evidently capable of continuing the process of producing, in connection with the bacteria which accompany it, more or less characteristic pathological lesions.

---

### The Need of Recreation.

A well-known financier some time since gave utterance to the statement that recreation was a needless luxury, a waste of time and money, and conferring no benefits mentally or physically. This expression of opinion on the part of the man of money naturally gave rise to much discussion, and the subject has been debated with considerable vehemence from every conceivable standpoint. It is superfluous to say that the consensus of opinion was against the views of the financier, and it was pointed out in both medical and lay journals that experience entirely controverted the assertion that recreation was useless. Indeed, the fact is too self-evident to need any argument that every man who works with his brains and leads a more or less sedentary life cooped up amidst the noise and turmoil of a great city, requires at least once in a year a respite from his nerve-wracking or monotonous labors. The wear and tear and stress and strain of modern business life in cities are exhausting to a high degree, and there are few who can endure them for long without incurring serious injury to health. The mental powers become worn, the body suffers in unison and unless a timely rest be taken, there will inevitably be a general break down. The wise man,

therefore, recuperates his fagged nervous system and his overworked body by means of a periodical change of scene and air. The physician in particular is by virtue of his calling a martyr to his profession. A busy medical practitioner is unable to call a minute his own, and is often compelled literally to snatch his rest whenever and wherever he can. The normal man or woman who lives amid the artificial conditions of modern civilized life will some time receive due warning that mental and physical powers are at high tension, and if further strained will give way, and complete collapse will be the result. The best plan is to take rest and recreation at the first symptoms of nervous exhaustion, but this course is seldom followed. So long as an individual remains at the scene of his work, he will continue at the treadmill, and thus the wisest procedure is at once to forego all business, and to seek fresh air and pastures new, in order to give the tired brain and impaired digestive system a chance to recover their equilibrium. To the ordinary person, as opposed to the mere money-making machine, an adequate amount of rest and recreation is more than a need, it is an absolute necessity.

### Education of the Unfit.

It is, of course, rank heresy to say anything in disparagement of the system of education—we might say overeducation—which prevails in this day and country. We are told that the public schools lie at the foundation of America's greatness, and in every municipal election in New York the stock reproach of the outs against the ins is that the latter have failed to provide adequate school accommodation for the children of the poor. But it may well be doubted whether our common school educational system is not, carried to its present extreme, productive of at least as much harm as good. We do not question the value of the three Rs, but how far beyond that the average child should be carried in his studies is a matter for grave consideration. In his recently published text book of psychiatry, Stewart Paton dwells upon the irrationality of our present system and he holds that there are numbers of children "seriously injured mentally and morally by a schooling ill adapted to their individual needs and necessities." "Every one admits," he says, "that it is the duty of the physician to warn those with weak hearts or lungs not to overtax those organs. Is it not equally important that the mental welfare of a community be safeguarded? Only some men are born to be educated; how many more, unfortunately, have thrust upon them an education which is disastrous not only to themselves, but also to the community at large!"

**Antidiphtheritic Vaccination.**—Bandi and Gagioni, speaking of the brevity of the immunity that is conferred by the injection of antidiphtheritic serum for prophylactic purposes, notwithstanding the experiments of Bandi with the bivalent serum, which have increased the curative as well as the preventive power of the serum, assert that they have attempted the preparation of a vaccine against diphtheria which shall confer a lasting immunity, that shall be effective. They conclude, from their experiments, that we can obtain in man and in animals by vaccination an immunity both antibactericidal and antitoxic against diphtheria without producing any harmful results. This immunity is constantly increased, the blood showing spontaneously a certain specific action against diphtheria. The immunity conferred by vaccination against diphtheria is more enduring than that conferred by prophylactic injections of antidiphtheritic serum.—*La Riforma Medica.*

## News of the Week.

**Dr. Bulkley's Lectures on Diseases of the Skin.**—The governors of the New York Skin and Cancer Hospital announce that Dr. L. Duncan Bulkley will give a series of clinical lectures on diseases of the skin in the Out-Patient Hall of the Hospital, Second Avenue and Nineteenth Street, on Wednesday afternoons, commencing November 1, 1905, at 4.15 o'clock. The course will be free to the medical profession.

**The Association of Life Insurance Medical Directors of America** held their Sixteenth Annual Meeting in New York City on Wednesday and Thursday, October 25 and 26, at the Academy of Medicine. Besides the general business, special papers were read as follows: "The Significance of Albumin and Casts When Found in the Urine of Apparently Healthy Applicants for Life Insurance," by Dr. Edwin Wells Dwight; "The Heart from an Insurance Standpoint," by Dr. Arthur Pell; "Albuminuria," by Dr. Thos. C. Craig. In addition to these papers the pamphlet entitled "Indications for Selection" was thoroughly discussed. The annual dinner of the Association was held on the evening of October 26 at the St. Regis Hotel. Special attention was given to this feature by Mr. Hahn, and it was a fitting close to a successful meeting.

**Yellow Fever.**—For the first time since yellow fever appeared in New Orleans the noon bulletin of October 28, covering the sixteen hours preceding showed that there were no new cases and no deaths. Dr. White and all the officers of the Marine Hospital Service were presented to Governor Blanchard at the St. Charles Hotel on Saturday, and afterward to Mayor Behrman at the City Hall. The ceremony was incidental to the departure of many of the surgeons from the city. The Governor has appointed Dr. White as colonel of his staff. In Panama there have been a few cases of yellow fever recently. Three men have died, and there are still several down with the fever.

**Consolidation of Charity Journals.**—After November 1, *Charities* of New York and *The Commons* of Chicago will be merged. The combined weekly journal will be more or less of a co-operative undertaking among those who know conditions first hand and are shouldering such movements as housing and child labor reform, the prevention of tuberculosis, and the social utilization of public schools. The editorship will be in the hands of Edward T. Devine of New York, and Graham Taylor of Chicago. To develop the educational work along national lines, a publication committee has been organized with Robert W. de Forest, former Tenement House Commissioner of New York, as chairman, and including Jane Addams and Margaret Dreier Robins of Chicago; Jacob A. Riis, Frank Tucker and Robert S. Brewster of New York; Daniel C. Gilman, Baltimore; Robert Treat Paine, Arthur F. Estabrook, Joseph Lee and John F. Moors of Boston; Simon N. Patten, Philadelphia; and S. W. Woodward, Washington.

**The Consolidation of "Climate" with the "Journal of Tropical Medicine."**—With the advent of the new year, the *Journal of Tropical Medicine* will issue four numbers annually, devoted especially to health and travel in warm countries. This is essentially the field formerly covered by *Climate*, a paper formerly edited by Prof. Chas. F. Harford, of Livingston College, who has been compelled to discontinue his journal because of the new public duties which he has undertaken.

**Erection of a Building for Chicago Physicians.**—The question of the establishment of a permanent medical home and library for the physicians of Chicago and Cook County was discussed at a meeting of the Physicians' Club, held October 23. Dr. Chas. L Dana of New York, the invited guest of the club, gave a brief history of the organization of the New York Academy of Medicine, and offered suggestions relative to the establishment of a similar organization in Chicago. After some remarks by Dr. Nicholas Senn, with reference to the establishment and maintenance of a medical library in such a club, a general discussion followed. It is proposed to make the building self-supporting from the rents received for private offices of physicians and surgeons, and at the same time to supply a place for the extensive and valuable library of the Chicago Medical Society, lecture and meeting rooms, club features, and rooms fitted up to take care of emergency cases and minor surgical work. Dr. Senn offered to be one of twenty to subscribe five thousand dollars each for the project. Dr. Daniel R. Brower proposed that the number be increased to one hundred supplying at once the means for beginning work. The trustees of the John Crerar Library, whose spokesman was Dr. E. S. Andrews, offered to take care of the medical library in the new building that will be erected on the lake front, and also to supply meeting rooms for medical societies.

**A Portrait of Dr. John Redman Coxe** has been presented by a grandson of the same name to the Medical Department of the University of Pennsylvania. Dr Coxe was born in Trenton, N. J., September 16, 1773 and was a student under the tutelage of Dr. Benjamin Rush. He was appointed Port Physician at Philadelphia in 1798, and he was for five years one of the physicians to the Pennsylvania Hospital. He was also a Physician to the Philadelphia Dispensary and Professor of Chemistry in the University of Pennsylvania. He was Professor of Materia Medica and Pharmacy in the University from 1818 to 1835. He was also a Trustee of the University and one of the founders of the Philadelphia College of Pharmacy.

**Bequests to Philadelphia Hospitals.**—By the will of David Teller of Philadelphia the sum of $250 is bequeathed to the Jewish Hospital. By the will of John Joseph Alter of Philadelphia the sum of $50,000 is devised to the Hahnemann and the Jefferson Hospital each, for the establishment of a John Joseph Alter Memorial, the character of which is left to the discretion of the trustees of the hospital. In addition the sum of $10,000 is bequeathed to each of the two hospitals named, for the endowment of two free beds, and also the sum of $10,000 to the University Hospital for the endowment of two free beds. By the will of Frances E Loeb the sum of $500 is bequeathed to the Jewish Hospital and to the Jewish Maternity Hospital. By the will of the late Samuel B. Seidenbach of Philadelphia the sum of $500 is bequeathed to the Jewish Hospital and the sum of $250 to the Samaritan Hospital

**A New Hospital Car.**—Recently a new hospital car was exhibited in Chicago by the Southern Pacific Railroad. This car can be transformed very easily into a parlor coach, and when it is not in use as a hospital car all of the berths and beds and the operating table are lowered beneath the floor, where they are stored. The floor sections of the berth space come up and form the head and footboards for the berths. The sections can be made up in single or double berths, and in place of the ordinary arrangements brass bedsteads may be substituted. Both lower and upper berths are provided with steel springs and the best mattresses. There is ample ventilation for both upper and lower berths, and either bed can be raised or lowered to any height desired. When the beds are in use the chairs and baggage are stored in the spaces beneath them.

**Patriotism vs. Humanity.**—As an instance of the intense earnestness of those who are struggling for liberty in Russia and of their hatred of the brutal Cossack defenders of the Government, it is reported that over two hundred physicians met in Odessa on Sunday last and unanimously resolved to refuse to aid any soldier, Cossack or military or civil official who is injured in fighting the people.

**Officers of the Chicago Gynecological Society.**—At the twenty-seventh annual dinner of this society, held at the Auditorium Annex October 20, the election of officers resulted as follows: *President*, Dr. Frank T. Andrews; *Vice-Presidents*, Drs. Joseph B. De Lee and Chas. E. Paddock; *Secretary*, Dr. Henry F. Lewis; *Treasurer*, Dr. Chas. B. Reed; *Pathologist*, Dr. Gustav Kolischer; *Editor*, Dr. Rudolph W. Holmes, *Councilor*, Dr. Franklin H. Martin.

**Chicago Surgical Society.**—The following officers were chosen at the annual dinner of this Society, which was held October 13: *President*, Dr. D. A. K. Steele; *Vice-President*, Dr. D. W. Graham; *Secretary*, Dr. Wm. Hessert; *Treasurer*, Dr. Frederick A. Besley; *Members of the Council*, the Secretary, the Treasurer, and Drs. L. L. McArthur, E. Wyllys Andrews, and A. J. Ochsner.

**The Tuberculosis Exhibition.**—The American Museum of Natural History has given the use of a large exhibition hall to the National Association for the Study and Prevention of Tuberculosis and the committee on tuberculosis of the Charity Organization Society for the American Tuberculosis Exhibition to be held from November 27 to December 9.

**Agnes Memorial Sanatorium.**—Not approving of the present policy of the institution, the entire Medical Board, consisting of Drs. Arnold Stedman, W. H. Bergtold, Carroll E. Edson, J. A. Wilder, and L. B. Lockard, resigned from the Agnes Memorial (Phipps) Sanatorium, Denver, Col.

**A Reception to Dr. von Noorden.**—The Medical Club of Philadelphia held a reception on October 25, in honor of Dr. Carl von Noorden of Frankfort, Germany.

**Resignation of Philadelphia Health Officials.**—Dr. Edward Martin has resigned the position of Director of Public Health and Charities in the city of Philadelphia. Dr. Charles B. Penrose has resigned as a member of the Philadelphia Board of Health. He is a brother of Senator Penrose, the leader of the Stalwart Republicans of Pennsylvania, between whom and Mayor Weaver of Philadelphia an interesting political conflict is going on.

**Dr. Josiah Calvin McCracken,** well known as an athlete and football player, has been selected by the Christian Association of the University of Pennsylvania to help establish a medical school in Canton, China. In this work he will be aided by Dr. A. H. Woods, who has been in Canton for some time, taking part in the work of the Canton Christian College.

**The Philanthropic Hospital** of William's Bridge, New York City, recently chartered by the State Board of Charities, was dedicated a few days ago in the presence of a large gathering of the medical profession and others interested. The old Jerome Hall, at Briggs Avenue and Maple Street, was

leased and remodeled, and it was this building that was dedicated. It is a frame structure, and has accommodations for twenty patients, with a house staff of six physicians and six nurses.

**The Ravenswood (Ill.) Hospital** was recently incorporated with a capital stock of $50,000. It is the intention and purpose to maintain a hospital and training school for nurses. The names of the incorporators are Drs. Geo. W. Green, Geo. N. Bussey, and Ernest A. Fetherston.

**A Long Island Sanatorium Association.**—The State Board of Charities has been asked to approve of the incorporation of the Long Island Open Air Sanatorium of Brooklyn, formed to furnish hygienic treatment for consumptives and to encourage work for the control of tuberculosis on Long Island.

**A Ruse to Pass Quarantine.**—A steerage passenger on a French liner some weeks ago was sent back to France because he had trachoma. Having heard that the inspection of cabin passengers was less strict, he took passage at Cherbourg on an American liner, his family being in the steerage while he came in the first cabin. His scheme was successful, for the quarantine officials passed him with the other first-class passengers on simple inspection. But he then went to the immigrant station on Ellis Island to get his family and was recognized by several of the inspectors who had refused him admittance before. He was detained and will be sent back again with his wife and children.

**Vaccine Virus Not the Cause of Tetanus.**—Dr. Henry A. L. Ryfkogel of San Francisco, in his report of the coroner of Oakland on a case of tetanus following vaccination, says that an examination of vaccine points taken from the same package as that whose use was followed by the tetanus showed that the virus was pure and free from germs. Both cultural and inoculation experiments were made without results.

**Sued for Graft.**—A physician of Spokane, Wash., has been sued for damages in the amount of $10,000 as a result of skin-grafting. The suit is brought by the man who furnished the pound of flesh, or, more exactly measured, 150 square inches of skin. It is alleged that the surgeon promised to remove only two or three strips, an inch wide and three or four inches long, but that, owing to the apparent willingness of the subject, he removed the entire graft from him, without waiting to anesthetize other persons who had volunteered to share with him in the sacrifice.

**Obituary Notes.**—Dr. J. Howard Taylor died at Philadelphia on October 24 at the age of 80 years. He was born at Kennett Square and was a brother of the late Bayard Taylor, the poet and traveler. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1852 and served in the Federal Army during the Civil War, retiring with the rank of major. Subsequently he was appointed Physician to the Municipal Hospital, retaining this position until he was appointed Quarantine Physician at the Lazaretto by Governor Curtin. Later he became a Medical Inspector of the Bureau of Health, and he continued his connection with the Health Department until his death.

Dr. Anne Ceridwen Rees of Union Hill, N. J., died suddenly October 19 of acute double lobar pneumonia. Coming from Wales, in 1893, she was graduated from the Woman's Medical College in 1898 and later practised medicine with conspicuous success. She was a pupil and protégée of Watcyn Wyn, a celebrated wit of Wales, and was herself a contributor to Welsh periodical literature.

Dr. William Titus of Newark died suddenly from apoplexy on October 28. He was 60 years old, and was born in Hackettstown, N. J. He received his education at Pennington Seminary and Jefferson Medical College, Philadelphia.

Dr. Giles Mebane McAden of Charlotte, N. C., died last week in this city of pneumonia. He was born in Graham, Alamance county, N. C., in 1867. He was prepared for college at Bingham Military school, and studied medicine at Baltimore Medical College, graduating in 1887 with high honors. After completing his college course he sailed for Europe, where he studied for six months. Dr. McAden's health never permitted him to practise his profession, although he always took a lively interest in medicine.

Dr. Vernon G. Culpepper of Norfolk, Va., died suddenly of apoplexy on October 15, at the age of 49 years. He was a graduate of the University of Virginia, and had practised in Norfolk for a quarter of a century.

Dr. Norman B. Scott of Hagerstown, Md., died on September 28, of old age. Dr. Scott was born at Bruceville, Carroll county, Md., May 8, 1819. He spent one year in the University of Pennsylvania, after which he entered the University of the City of New York, and was graduated from that institution in 1844, with the degree of doctor of medicine. Immediately after his graduation Dr. Scott went to Hagerstown and began the practice of his profession, which he carried on continuously for 50 years, retiring in 1894.

## Correspondence.

### THE INTERNATIONAL CONGRESS OF TUBERCULOSIS.

(From Our Special Correspondent.)

Paris, October 10, 1905.

The impressive opening of the International Congress of Tuberculosis took place in Paris at the Grand Palais on October 2. The President of the French Republic presided. The most brilliant representatives of the political and scientific world were among those who attended. Dr. Herard, President of the Congress and Dean of the Academy of Medicine, gave the opening address, in which he traced the history of the struggle against tuberculosis in different countries and explained the different lines of work of the Congress. Thirty-three countries had responded to the invitation from France and had sent their delegates. In turn the following men gave addresses: Schjerning of Germany, Williams of England, von Schrotter of Austria, Beco of Belgium, de Gouvea of Brazil, Rousseff of Bulgaria, Espina y Capo of Spain, Beyer of the United States, Hutyra of Hungary, Baccelli of Italy, Davel of the Argentine Republic, Heinsen of Sweden, Schmidt of Switzerland, Babes of Roumania, Raptchinski of Russia, Siah-Cmun-Tsit of China and Sponck of the Netherlands. Professor Maurice Letulle, General Secretary of the Congress, explained the organization of the Congress and the methods of its work. In his eloquent address he declared that the Congress had presented to all peoples the idea of the unity of all races in their fight against tuberculosis, the worst of human maladies. He demonstrated the absolute duty, which is incumbent on every civilized nation, of struggling against this dire disease. Finally, the President of the Republic delivered an address in which he expressed, in the name of France, thanks to the Sovereigns and chief rulers of the various countries represented, and best wishes to all of the visiting delegates.

The Congress was a great success for its organization was perfect, being the outcome of long preparation. The "National Committees" had been organized so that they could clearly represent their countries on this question. The French territory had been divided into "regional committees" for the same purpose. The Congress was divided into four sections: Medical pathology, presided over by Professor Bouchard; surgical pathology, Professor Lannelongue; preservation of infants, Professor Grancher; preservation of the adult, Professor Landouzy and Senator Paul Strauss. The four sections met simultaneously, each

in its own apartment. There were seven meetings for the discussion of the reports and the presentation of the communications. On the next day the work of the Congress began in the four sections. The number of communications was so incredibly great that the names as well as the work sent in had to be passed over.

In the first section, medical pathology, after the address of Bouchard, the question of the biology of the bacillus of Koch and of the paratuberculous bacilli was discussed. Professors G. Ferre of Bordeaux, Courmont of Lyons, Doctor Lydia Rabinowitsch of Berlin, and Professor Behring of Marburg, presented the results of their researches and observations. The two sections of medical and surgical pathology united to listen to the communications concerning the relations of human and animal tuberculosis.

At the meeting in the afternoon, which was presided over by von Leyden, Albert Robin spoke concerning the constitutional and individual conditions predisposing to tuberculosis and the means of modifying them. His experiences have led him to think that while conditions antagonistic to tuberculosis, for example arthritism, diminish the respiratory changes, on the contrary, respiratory changes are increased in all tuberculous subjects. Arloing and Laulanie, Charrin and Tissot, moreover, gave the results of their experiments with animals by which they endeavored by the administration of suitable medicaments to lessen these changes. The results of these workers, however, were not always in accord with those of Robin. Consequently, before drawing definite conculsions it was decided that all of these authorities undertake again control experiments, reporting the results at the next Congress.

In the section of surgical pathology, Professor Lannelongue presiding, Professor Arloing of Lyons, Dr. Mazyck Ravenel of America, and Professor Kossel of Giessen, presented their reports on the comparative study of the diverse kinds of tuberculosis. After the discussion of these papers, the sections of internal and external pathology voted almost unanimously on the absolute necessity of prophylactic measures against bovine tuberculosis, and called the attention of the public authorities, which for the time being have been influenced by the theories of Koch, to the importance of renewing their former vigilance and of redoubling their care in the fight against animal tuberculosis.

The third section, which discussed the protection of the infant from tuberculosis, was presided over by Professor Grancher. A. B. Marfan of Paris, and O. Heubner spoke on this important subject. Afterwards Professor Vallee of Alfort reported an entire series of experiments in relation to the origin of tuberculosis of the tracheobronchial ganglia in cattle, concluding that this affection is almost always of intestinal origin in the calf and that consequently a strict surveillance of milk, which is so often full of bacteria, is necessary.

The fourth section, which was concerned with the protection of the adult, and social hygiene, was presided over by Senator Paul Strauss and Professor Landouzy. Millerand, President of the Commission of Social Assurance of the Chamber of Deputies, and Professors Brouardel, Peyrot, and Emile Cheysson, of the Institute, and members of numerous mutual aid associations of all countries spoke. The appearance of these men, a new element in the Congress of Tuberculosis, had a profound influence on the trend of the discussion.

The subject of life assurance and mutual aid in the struggle against tuberculosis was discussed. Edouard Fuster of Paris, gave a brilliant résumé of the subject in the name of France. He believed that the object of these associations for the workingman should be to prevent the disease. The meeting in the afternoon was devoted to the reports presented by Romme of Paris, Newsholme of Brighton, and Sternberg of Vienna, concerning the etiological factors of tuberculosis and the economical conditions in the social etiology of tuberculosis. The domestic origin of the disease from its various points of view—unhygienic dwellings, alcoholism, and so on, were discussed.

After these meetings the members of the Congress were received at the Hotel de Ville by the Municipality. Henri Russelle, Vice-President of the Municipal Council, assisted by Barbier, President of the General Council, Lepine, Prefect of Police, and others, presided over this reception. The exchange of ideas at this meeting was most helpful. Later the delegates went to the various soirées which were given by their French confreres.

On the second day of the Congress, the first section had so much work on hand, that it was obliged to divide itself and form another section on therapeutics, which held its meetings in a special hall and was presided over by Professor Gilbert and Professor Roger.

The relation of social problems was the subject of discussion in the fourth section, especial attention being paid to the rôle of dispensaries and of sanatoriums in the antituberculous war, and the hygiene of the tuberculous who are massed together. The technical sections were of equal importance. At the first section, that on medicine, the question of the early diagnosis of tuberculosis by new methods was discussed. The speaker, Doctor Achard of Paris, insisted on the greater importance of the older methods of diagnosis, notably, auscultation, inspection, and the like. Radiodiagnosis was most valuable, also, but the absolute sign was the presence of Koch's bacillus, determined by means of the microscope or by the inoculation of animals. Afterwards two reports were read on the rôle of dispensaries and sanatoriums for this disease. Courtois-Suffit and Laubry of Paris, concluded that the sanatorium ought not to be considered as the chief instrument in the antituberculous war. It ought to serve the purpose of sheltering those threatened by tuberculosis, that is, it ought to be a sanatorium for preservation but not for cure. The existence of the sanatorium was of little service unless residence in it was preceded by local measures which would change the life of the poor, that is, general hygienic measures which provide air and light. Other reports on this subject were presented by Sophus Bang de Silkeborg and Beco of Brussels.

In the second section, surgical, ileocecal tuberculosis was discussed in the papers of Doctors Roux of Lausanne, Depage and Pinchart of Brussels, and (préservation scolaire) A. Demoulion of Paris. In the third section the scholastic prophylaxis was the object of discussion (preservation of the infant). Very interesting papers were read by H. Mery of Paris and Ganghofner of Prague.

On the fourth day at four o'clock the President of the Republic in the presence of a large number of delegates dedicated the Emile-Loubet Dispensary founded at Paris, for tuberculous patients, by the individual subscription of 140,000 mutualists. At half after eight in the evening the delegates met at a theatrical performance at the Theatre du Chatelet which was given by *le Matin*.

Thursday was entirely given up to excursions. The delegates made up various parties, some visiting the sanatorium of Bligny, others going to Berck-sur-Mer, others to Ormessen, and still another group accompanied by the President of the Republic went by a special train to visit the antituberculous sanatorium of Monigny-en-Ostrevent, built according to the plans of Calmette. The members of the sporting columns of the political papers together with the members of the Antidust League organized an excursion in automobiles in order that the delegates might observe the various methods of laying the dust by means of tar and oil which have been made use of on the thoroughfares of Paris and its environs.

Friday evening a banquet of four hundred and fifty covers was given to the delegates, Dr. Herard, President of the Congress, Ruau, Minister of Agriculture, Casimir-Perier, and Léon Bourgeois being present.

Finally on the afternoon of Saturday, October 7, the Congress closed with an impressive meeting held at the Grand Palais which was presided over by Dr. Herard. It was at the beginning of this meeting that Professor von Behring made a sensational communication on the cure of tuberculosis by a new remedy. This had to do with a curative principle depending upon the impregnation of living cells of the organism by a substance taking its origin in the virus of tuberculosis which the author named TC. When TC became an integral part of the cells of the animals treated by it and when it was metamorphosed by these cells the author designated it by the name TX. In the bacillus of tuberculosis TX or rather TC preexisted as an agent endowed with fermentative and assimilative qualities. A fundamental fact was that TC, not reproducible, possessed nevertheless the power of giving rise to a tubercle which, however, formed in this way did not become caseous or soften. TC could be elaborated in vitro so as to make a remedy which could be applied without danger in human therapeutics.

After the votes of different sections were taken Professor Baccelli, former Minister of Public Instruction in Italy, thanked, in an eloquent speech, the organizers of the Congress and the representatives of the public powers for the reception which had been given in France for the foreign delegates. The Congress decided that its next reunion should take place in Washington in 1908.

That evening the President of the Republic gave a dinner at the Elysées in honor of the members of the Congress, the dinner being followed by a very brilliant reception. On the next day, October 8, the *Journal* offered to the members of the Congress the use of a special train, "Paris-Côte d'Azur" which carried almost two hundred delegates, both French and foreign, to visit the sanitary establishments and sanatoriums in the interior of France. Finally, in order to place the public in touch with the works of the Congress, practical conferences in social hygiene were carried on every day in the afternoon at the International Exposition at the Grand Palais, where was organized an exposition comprising everything that had to do with tuberculosis,—its history, its nature, its prevention, and its treatment. This exposition was officially inaugurated by the

President of the Republic on the opening day of the Congress. This exposition comprised a scientific section with admirable exhibits from the collections of the faculty of medicine of Paris, from the Depuytren Museum, from the Museum of Natural History, from the Veterinary School of Alfort, and from the Pasteur Institutes of Lille, Paris, and Nantes. Likewise, the Universities of Munich, of Anvers, and of Birmingham, sent very interesting exhibits. It was indeed a veritable museum of tuberculosis which gave the opportunity of studying step by step the work of masters of all countries. Of especial interest were the admirable exhibits from the laboratories from Munich and Berlin. There was, besides, a section relating to prophylaxis devoted to the leagues and societies of propaganda, works of social hygiene. Another section was given up to the improvements that have been made in relation to domestic hygiene. And finally an industrial section was devoted to alimentation and to the cleansing and disinfection of public establishments and to the improvement of the methods of transportation in relation both to railroads and to hotels. This exposition was most important and spoke with eloquence to the observer.

## SEVENTY-SEVENTH CONGRESS OF GERMAN NATURALISTS AND PHYSICIANS.

(From Our Special Correspondent.)

TENDON TRANSPLANTATION—ILEUS—GANGLION—VARIOUS ABDOMINAL OPERATIONS—INGUINAL HERNIA—GALLSTONES—RENAL TUBERCULOSIS—OPERATION ON THE PITUITARY BODY—RADIOGRAPHS OF THE BLADDER.

MERAN, October 10, 1905.

THE seventy-seventh annual congress of German Naturalists and Physicians, held at Meran, Tyrol, on September 24 to 30 was not so well attended as many of its predecessors. At last year's meeting at Breslau an attendance of over 3,000 was registered, but only about 1,400 visitors were present at the Meran sessions. This was, no doubt in large part due to the remote situation of this beautiful little health resort, which is the smallest city in which a meeting of the society has ever been held. The number of papers read was, as usual, very large, and only some of the more important will be mentioned here.

In the section on surgery Prof. Adolf Lorenz of Vienna spoke of the indications for tendon transplantation. He said that the measure was not one to be undertaken lightly, for it was first necessary to know exactly which muscles were irreparably paralyzed and which ones might, to some extent at least, recover. This could be decided at once, and Lorenz therefore advised that attempts be made first to restore the normal form of the contracted and paralyzed limbs, and that every muscle susceptible of improvement be restored to its function. Only after this had been done was it possible to pick out the permanently weakened muscles and to consider the advisability of a tendon transplantation. The operation itself was extremely simple. The restoration of form to the damaged limb and the operation, should be two entirely distinct acts, often separated by an interval of months. Lorenz had often had it happen that patients had had their expectations so far surpassed by the bloodless procedure of correction by manipulation that they have declined the tendon transplantation. In partial palsies of the upper extremity, however, particularly of the hand, the transplantations have a very broad field.

Prof. Hofmeister of Stuttgart reported on the results of early operation in complete intestinal obstruction. Of twenty-seven patients operated on the first day twenty were cured, and of sixteen patients operated within the first three days none died. The most important factor in the treatment is putting the patient in the surgeon's hands as early as possible.

Dr. Küttner of Marburg spoke on the prognosis and treatment of ganglion, and said that excision, incision, and crushing by a blow all gave about the same results. In the discussion Dr. Lexer expressed himself strongly in favor of excision, which is always practised at von Bergmann's clinic in Berlin. Dr. Ronzi of Vienna discussed the results obtained by Bunge's method of forming amputation stumps. In twelve cases of amputation below the knee done in this way at von Eiselsberg's clinic the stumps were all found insensitive to pressure or percussion, and the results were equally favorable in eighteen amputations through the thigh. Dr. Harberer of Vienna spoke on the treatment of sarcoma in long bones. On comparing the results in cases that were treated conservatively and by mutilating operations it was found that simple excision was as satisfactory as amputation.

Professor Wilms of Leipzig discussed the mechanical factors in post-operative intestinal obstruction. For a proper comprehension of the different forms ileus must be divided into paretic and mechanical varieties. The first is seen in extensive atomy of the bowel, but for paresis of shorter stretches kinking or twisting with valvular closure must also be present. Knowledge of the mechanical factor is often of greater importance, as in those cases of mechanical atomy simple enterostomy may give relief. Dr Hartle of Graz spoke on blunt injuries of the intestine. A case of especial interest was one of avulsion of a portion of the small intestine, treated by intestinal resection and followed by recovery. Another case was one of rupture of the spleen, caused by falling on the abdomen. Suture of the spleen was followed by recovery. A great rarity reported was a retroperitoneal injury of the duodenum. Dr. Brenner of Linz described three cases in which, at a second laparotomy performed for other causes from one to three years later, he was able to assure himself of the complete cure of gastric ulcers for which a gastroenterostomy had previously been done. He concluded that gastroenterostomy is as valuable a measure in the treatment of indurated ulcers as resection of the lesions. Brenner performed twenty-one resections of ulcers with 28.5 per cent. mortality. Of the survivors, 65 per cent. remained well over a year later. Of thirty patients treated by gastroenterostomy, fourteen remained well a year later. He considers that gastroenterostomy should be performed first, and only if this proves ineffectual should resection be resorted to. In a second communication the same author took up the radical cure of inguinal hernia. In the period from 1892 to 1903 Brenner operated on 1,080 men and 108 women for inguinal hernia, usually bilateral, so that the number of operations was about 2,000. He used his own modification of the Bassini operation. The period of convalescence was usually seventeen days, and the mortality, including operations in strangulated hernias, was .9 per cent. The number of cures, that is, nonrecurrence in two years or more, was, in men, 91.8 per cent., and in women 95 per cent., or 92 per cent. for both; a figure midway between Bassini's claim of 90.1 per cent and Kocher's of 92.5 per cent.

Dr. Fink of Carlsbad reported on 385 cases of gallstones treated by the usual Carlsbad cure. In most instances he found that there was not only disease of the biliary passages, but also of the liver itself. He pointed out the effectiveness of the Carlsbad waters in the treatment of these cases, and expressed the opinion that operation was indicated only when the Carlsbad cure had proved ineffectual, when there was empyema of the gall bladder, or when chronic obstruction of the duct existed. Dr. Guleke of Berlin described some interesting experiments performed at the clinic of von Bergmann. These led to the conclusion that the cause of death in acute pancreatic diseases was due to an intoxication depending on the formation of poisonous degenerative products in the organ itself. The insertion of a pancreas into the abdomen of another animal in a short time gave rise to severe general symptoms and death. He had also succeeded in producing an immunity in the animals against this pancreatic intoxication.

Dr. Goldner of Vienna, in discussing the occurrence of traumatic inguinal hernia, expressed himself as believing in the possibility of its occurrence, and formulated the following conclusions: Inguinal hernia is usually congenital, or, in older cases, it is the result of slowly progressing weakness of the muscles. Only very rarely is it the result of direct trauma, which is then really to be regarded as an injury to the abdominal wall. Dr. Preindelsberger, in reporting a very large number of vesical calculus operations, stated that the procedure to be employed depended entirely on the nature of the individual case and the consistency of the stone. He performed most of his operations under spinal anesthesia, and was very well satisfied with the results. In the discussion, Drs. Hirsch of Vienna and Dr. Defraceschi of Rudolfswert, also described very good results with spinal anesthesia.

Professor Zuckerkandl of Vienna demonstrated twenty-three tuberculous kidneys removed by operation. He called attention to the frequency with which the renal disease is complicated by tuberculosis of the ureter, and to the interference with healing of the wound caused by the ureteral stump if left behind. He, therefore, recommended the routine excision of the ureter and described the technique of the operation in detail. In a second paper, Zuckerkandl described twenty cases of perineal prostatectomy, and said that prostatectomy is now the only certain method of relieving all the forms of urinary retention due to hypertrophy of the gland. Drs. Lichtenstern and Katz of Vienna reported on observations undertaken to determine the value of phloridzin in the functional diagnosis of renal affections. In testing the appearance of phloridzin diabetes they found that healthy and diseased kidneys reacted similarly.

A more purely theoretical subject, since it dealt with studies in the cadaver, was presented by Dr. Schlosser of Innsbruck, who considered operations on the hypophysis. He believed that there were cases in which an operation on the hypophysis might come in question. While the normal gland is not accessible, the enlarged pituitary body in acromegaly projects, downward and forward, and would be easier to reach. Such an operation would be promising,

since it is known that in acromegaly the enlargement is due to an adenomatous and not to a sarcomatous change. The approach is easiest from in front. If the optic nerve is atrophic the orbit may be cleared out, and thus plenty of room be given, but even if the nerve is intact the inner wall of the orbit may be chiseled away, and the contents of the cavity be pressed outwards, so that even in these cases the access to the gland would be good.

Dr. Voelker, of Heidelberg, presented some radiographs of the bladder that were of exceptional clearness and interest. They were obtained by injecting an organic silver solution into the viscus before making the exposure. In this way he obtained one beautiful series showing the normal form of the organ, another of different stages during the act of emptying the bladder, and finally a series showing unusual distortions of the organ in women having pelvic affections. Voelker even succeeded in throwing the solution into the ureter, and so obtained pictures of the renal pelvis. In two cases of floating kidney curvature and dilatation of the ureter could be distinguished.

## OUR LETTER FROM THE PHILIPPINES

(From Our Special Correspondent.)

MANILA, P. I., September 15, 1905.

SINCE the letter of September 7 there has been a rapid decline in the number of cases of cholera occurring in the city of Manila. On September 8, there were nine cases, from which the number has gradually dropped until two days ago, since which time there has been an entire absence of the disease.

Probably one of the most satisfactory results obtained by the fight made against cholera, was the eradication of the disease from Bilibid prison by the application of sanitary rules. The conditions which confronted the health officials, when they took charge of the institution, were very discouraging. Between August 23 and September 1, there had been from two to five cases of cholera daily. The prison is built upon low ground, and after there has been a heavy rainstorm at a time when the tide is high, a good portion of the prison grounds is under water. There are no flush closets for the use of the prisoners, and most of the latrines consist of open tubs placed in the sleeping quarters of the inmates. Flies were plentiful. The circumstances were such that it was difficult to issue the food to the inmates in other rooms than those in which they had their sleeping quarters and performed their toilets. The latrines contained disinfectants, yet it was possible for infected flies to pass from the latrines to the food, during the time it was served. The health officials decided to attempt to combat the disease almost entirely by waging warfare upon the flies. Each of the latrines was screened, and large sheets of sticky fly-paper were hung about the interior. Entrance could be had only by passing through a screened vestibule fitted with screen doors placed at each end. In that way, all the flies which were likely to convey infection were confined to the latrines, and in addition, this element of danger was soon removed by their falling victims to the fly-paper. As an extra precaution, the latrines located in the yards were protected in the same manner.

In addition, all the bamboo bunks were scrubbed with a lye solution, and afterwards soaked with a one to one-thousand solution of bichloride of mercury. The walls were thoroughly whitewashed. The prisoners were bathed in a bichloride solution, and all their body clothing, blankets, and other textiles with which they came in contact, were immersed in a bichloride solution. A cholera hospital was improvised, and that was also thoroughly screened. After these measures had been carried out, no further cases of cholera occurred.

The Manila water supply was threatened a number of times during the past week on account of cases of cholera being discovered in the water-shed. Fortunately, however, the casese were detected in time, isolated, and the stools properly disinfected. The great danger to which Manila is exposed by having the water-shed thickly populated, has again been brought forcibly to the attention of the public by the cholera epidemic of the past few weeks. The present condition of affairs is a constant menace, not only on account of cholera, but on account of typhoid fever and other water-borne diseases.

A circumstance which may throw some light on the origin of the present outbreak, is the fact that the last case of cholera during the former outbreak, occurred April 18, 1904, at Malabi, Laguna, while among the very first cases, this time, were those which occurred at Jala Jala, Rizal, which is significant because the two places are separated by a distance of less than ten miles.

The Manila Medical Society held its first monthly meeting since the adjournment which took place last April on account of the hot season on the evening of September 11, at the Saint Paul's Hospital. The evening was devoted to the informal discussion of the cholera situation, and was opened by Dr. V. G. Heiser. Drs. R. P. Strong and Paul Freer, Colonel Byrne, Commissioner Worcester, Dr. Wilkinson, and others participated in the discussion. The history of the present epidemic was given briefly, the substance of which was about the same as that already stated in previous letters.

Dr. R. P. Strong, the director of the Biological Laboratory, read a paper upon cholera vaccine. He stated that the preparation and manufacture at the local laboratory differed from all others heretofore produced, in that it caused practically no local reaction, and gave a much higher degree of immunity. The duration of the immunity is estimated to be about six months. In order to test this serum practically, one-half the inmates of Bilibid prison are now undergoing vaccination with the anticholera vaccine, and in the event that there should be another outbreak of cholera in that institution in the future, it is hoped some conclusive evidence may be obtained as to the efficacy of this vaccine in human beings. So far there has been no test made in human beings.

## THE ETIOLOGY OF TABES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the issue of the MEDICAL RECORD of October 21 there appears an article on the Etiology of Tabes, etc., by Dr. F. von Raitz, which contains so many statements that are not in accord with accepted fact that I am constrained to ask you to allow me space to correct some of them. The writer undertakes to speak authoritatively on the subject of the etiology of tabes. What his experience has been to warrant the presumption I do not know, nor am I able to infer from a reading of the article. He says, "The apparent establishment of tabes is, therefore, not a natural consequence of progressive science built on pathological facts, but a result of dogmatic ruling." I agree with him that the relationship of syphilis to tabes is not built on pathological facts. It is built on actual facts. I am familiar with the tabes-syphilis question and I know of no dogmatic statements concerning it that are not based on enormous experience. Erb and Fournier are the two writers who speak most dogmatically about it, and each of them has had an enormous experience. The latter bases his statements on a study of upward of 1,000 cases, while the former has had probably the widest experience of syphilis of any physician in the world.

The writer of the article further says, "Those who accept syphilis as the cause of tabes have no difficulty in finding syphilitic evidence in everybody who has tabes." This statement is far from the fact. I am one of those who accept syphilis as the cause of tabes, and yet I often encounter great difficulty, indeed the greatest difficulty in finding any evidence of syphilis in about one case out of every ten that I encounter. Dr. von Raitz is sure that "the actual cause of any disease is not determined by opinions and theories but by pathological facts alone." I suppose he would have us believe that in such a way the cause of diphtheria, of yellow fever, of syphilis itself, and almost numberless other diseases was established, but he should furnish some reason why this should be believed more than his say so. Again he says, "I believe that no one of those who make syphilis responsible for tabes has ever examined a syphilitic cadaver, perhaps not even a tabetic cadaver, and all that modern writers on tabes say is quotation." Such a statement is too absurd to be believed by anyone. I for example am a modern writer on the subject of tabes and that Dr. von Raitz may be purged of the above quoted opinion, I may say to him that every year since 1893 I have examined not one but many syphilitic and tabetic cadavers, and to my personal knowledge many of my fellow neurologists have had similar and larger experience, an experience which they would probably consider an essential before they spoke or wrote on the subject. Such speaking or writing would otherwise be considered no less effrontery in themselves than it is in others who discourse on the matter as if they had had experience that would entitle them to an expression of opinion. I shall not encroach upon your space to the extent that would be required to point out the scores of fallacies that exist in the article in question on the way in which tabes flows out of syphilis. It might be profitable to do so if nearly every paragraph did not contain a statement without the slightest foundation in fact. For instance, "Syphilis everywhere presents itself as a blood disease." In what, I should like to ask, is the reaction or constitution of the blood in an individual who has had syphilis different from that of the individual who has not had syphilis? Is there any book on hematology that describes syphilitic blood? Has anyone ever claimed that the syphilitic virus *per se* causes tabes? I never have heard of anyone who has made such a claim. Again he says, "Inquiry into the previous histories of tabetics teaches us that many tabetics have practised coition excessively." Does it? If it does, I

should like to ask the constitution of "us." It is barely possible that my experience, based upon a study of some 400 individuals with tabes, may entitle me to speak. If it does I should like to say that such inquiry on my part gives no such information. And while we are on this subject I clamor for enlightenment: what constitutes "excessive coition?" A gentleman of my acquaintance, 50 years old, considers that he has been very temperate in that direction, about once a day for forty years. Another, 43 years old, tells me he thinks that about eighteen times a year is about the figure. Both of them are healthy, vigorous men. Then again "Sexual impulses descend from the brain to the center of ganglionic cells in the gray matter, and from those cells along the nerve fibers of the posterior columns, through the posterior nerve roots to the genital apparatus." This is so alluring that I hesitate to touch it, but in view of the fact that those of us who are engaged in the study and teaching of physiology and neurology have been led to believe that the posterior roots and the posterior columns convey impulses upward only, *i. e.* toward the brain, I am constrained to check the inhibitory impulse that I had on first reading it.

But we must leave this portion of the article, even though it contains attractive statements (not original with the writer) as, "All matter is chemical, and life in its various forms of existence, is nothing but the result of chemical action," to come to the real motive of the author's paper, viz., that tabes is not infrequently due to trauma; "How a simple fall can cause injury to the cord and consequently tabes, is not difficult to understand." To which I reply it seems to be difficult to me. I bring an open mind to the subject, and that may account for the difficulty. But when I recall that there are only approximately twenty-one cases of tabes on record in the world's literature which deserve to be considered at all from this point of view, according to the consensus of opinion of those who ought to know most about it, viz., those who devote their best efforts to a study of the disease, perhaps I am not presumptuous in assuming that many other neurologists have a similar difficulty. "That traumatism is being recognized as an etiological factor of tabes, is proven by a few cases awaiting compensation for damages by the court." There is a delightful naiveté about this, which appeals to me. Were it not that I am the "prominent neurologist" referred to in the writer's description of one of these cases, I should say nothing against the proof "of the traumatic origin of tabes." The case is still within the jurisdiction of the court, therefore I do not feel free to discuss it in the public prints. I wish, however, to deny emphatically that I advised the company in whose vehicle it is claimed the woman was injured to make compensation for inflicting the disease which she had when I examined her, viz., tabes, and for the adequate reason that I did not and do not believe that the fright and shock which she was said to have received had anything to do with initiating that disease. No more did I believe that the Mrs. B. of Dr. von Raitz's text who was "spirited" away to prevent her appearance in court according to the suspicious lawyer of Miss H., and who was very kindly sent to me for examination by Dr. von Raitz, owed her tabes to the fall on the sidewalk from slipping on a banana peel, and for excellent and adequate reasons which I do not feel called upon to relate here.

The individual who believes that the Argyll-Robertson pupils, the tendon-jerks, and the sphincteric symptoms of tabes can develop and reach a very complete stage in three weeks, has a conception of tabes that transcends my understanding. He likewise, in my opinion, has had very little real experience with the disease. If the history of a fall or an injury is all that one wants to be convinced that tabes flows from such accident, what more illustrious instance could one ask for than the following: A gentleman of large affairs in the city, whom I have known professionally for fifteen years, was thrown by the sudden jolt of a car on the elevated railway to his back and with such violence that he was laid up for a fortnight. An insurance company paid him for two weeks' total disability. I saw him the day after the accident. He had two bruises over the lumbosacral spine and complained of being very sore. When he learns a month or a year hence that he has tabes, why shouldn't he attribute it to the injury, why shouldn't Dr. von Raitz attribute it to the accident if he is consulted by this gentleman? There are many reasons why I should not look upon it as being due to the accident, the most important being that I have had him under treatment for tabes for upward of three years. The fact that he has the disease is known to his family but for reasons that I do not feel called upon to specify here, he is still in ignorance of it.

I have trespassed upon your space, so I shall draw gently to a close. I say gently, for were I to do so abruptly I should neglect the opportunity to say that there is such a disease as pseudotabes following diphtheria, malaria, typhoid fever, and other infectious diseases, but so far as I am aware its existence of occurrence has heretofore never been used as an argument in favor of the occurrence of tabes from sexual excesses and irregularities! But then if I were to close less abruptly I should have something to say about the case of Miss Ida F., whose history is related upon p. 652 of your journal, and whom I saw (at least I saw a lady of 40 who bore that name) several years ago in consultation with the late Dr. C. S. Elebash. I think I know the cause of her tabes, and as Dr. von Raitz asks the question "was diphtheria, typhoid fever, or excessive masturbation the real cause," I answer: "None of them was. The man with whom she had sexual intercourse when a girl died of general paresis, and that disease didn't come from diphtheria either!

JOSEPH COLLINS, M.D.

37 WEST 54TH STREET.

## Progress of Medical Science.

*Boston Medical and Surgical Journal, October 26, 1905*

**A Review of the End Results in Cases of Exophthalmic Goiter Treated Surgically.**—T. W. Huntington reports nine cases. Eight of the patients are still living. An analysis from the standpoint of end results has brought out the following facts: Exophthalmus was present in seven cases. At the present time it is absent in four, and notably lessened in three. The average duration of the disease prior to operation in the first series was eleven months, in the second twenty-eight months. Hence, it may be inferred that permanent deformity from this cause may be expected in long-standing cases. Tachycardia disappeared after a few weeks in every case. The same statement may be made in reference to abdominal psychic manifestations, undue excitability and associated nervous phenomena. Recurrence of thyroid hypertrophy was noted in one case necessitating a third operation thirty months after the second. It may be that a more radical removal of the right lobe originally would have obviated the final procedure. Reestablishment of normal structural conditions as manifest in muscle repair, increase in weight and strength, and resumption of normal blood conditions has been uniformly slow. While in each case progressive improvement in these respects has been noted, two patients have been disabled to such an extent that they will never regain their wonted standard of health.

**Mercuric Cataphoresis in Diseases of Women.**—Case reports are given by F. B. Carleton. He coats the positive electrode with mercury, making it aseptic before each treatment. The patient should take a saline douche an hour or two before coming for treatment. The author claims that the medicinal agent from the electrode is carried directly into the diseased parts. We obtain, therefore, a double effect; first, the sedative, stimulating and tonic effect of the electric current *per se*; and second, the antiseptic and astringent effect of the oxychloride of mercury, which is forced into the tissues in its nascent state. Cases reported include uterine subinvolution, painful ovaries, prolapsed uterus and adnexa, cystocele vaginal atony, endometritis, etc.

*New York Medical Journal, October 28, 1905.*

**Abdominal Incision for Tuberculous Peritonitis.**—This subject is discussed by S. Lloyd, who finds on looking up the histories of twenty-one cases with which he was familiar, that seventeen were discharged cured—that is at the time of their dismissal from the hospital there were no signs of tuberculous disease present, and their physical condition had improved so much that they could be classified as cured. Four of these patients, however, had been from the author's own private practice and—although dating back only two years—they had been under observation and remained well. Such a statement is impossible, naturally, with ordinary hospital patients and the ultimate outcome of the other thirteen he is unable to answer for. One was discharged improved, being taken from the hospital by his parents before he was thoroughly satisfied that the operation had been successful. All of these cases were of the miliary type. The chronic tuberculosis cases were but four in number—two patients died and one was discharged unimproved, the latter at the time of his leaving the hospital was showing marked symptoms of general tuberculosis. Two of the patients were treated medicinally—one was cured and the other died.

**The Treatment of Hay Fever.**—L. Weigert Sterne deduces from the reports on the use of Dunbar's serum conclusions which lead him to advocate the use of bicarbonate of sodium, in powder (or saturated solution), alone, or with the addition of one grain of cocaine to the drachm. This is to be used as a snuff whenever the symptoms appear. The solution may be used in a nasal douche

or throat atomizer. Irritable eyes may be bathed with the same solution. General hygienic and dietetic rules should be observed.

*Medical News, October 28, 1905.*

**The Diagnosis and Treatment of Anemia.**—Harlow Brooks describes the chlorotic and secondary anemias, discussing their respective causes and clinical courses. In speaking of treatment he lays special stress upon the need of fresh air and sunlight. In the warm months, children can go about with almost no clothing. To the foregoing carefully supervised exercise may be added, except in those instances in which we find renal or cardiac changes. Here rest and quiet are indicated. Change of habitat and climate is desirable in many cases. The gastroenteric tract must be carefully regulated. Gastric atrophy or dilatation are often present, calling for lavage and associated local measures. Predigested foods may be required with intestinal medication. Nitro-muriatic acid has yielded excellent results in some cases of pernicious anemia. Abnormal fermentation in the bowel should be checked, as we thereby limit the transformation of certain amounts of iron in the food into the insoluble iron sulphide. Saline aperients assist us in this direction. The diet of each individual case must be made the object of careful study. Foods rich in albuminous iron should be selected. Milk as an exclusive diet is not advised. Strictly medical treatment is often disappointing. The kind of iron is of secondary importance so far as concerns chlorosis and the simple acute secondary anemias. Inorganic preparations have given the author the best results. Mercury and arsenic are often valuable adjuvants in severe and chronic cases. The author has never seen any benefit follow oxygen inhalations.

**The Gopher; A Possible Substitute for the Guinea Pig.**—S. W. Hewetson makes a preliminary report on the subject of using the gopher instead of the guinea pig for animal experimentation in tuberculosis, as in certain parts of the country they are more easily obtained than are the latter animals. A series of inoculations was made and its results analyzed. The author says that his work distinctly proves the susceptibility of the gopher to tuberculosis, and places in the hands of medical men residing in the gopher belt an additional aid in the diagnosis of obscure cases, be they renal, pulmonary, or glandular. Its use would be limited to cases in which the presence of tubercle bacilli could not be demonstrated with the microscope, owing to their being present in small numbers. To obtain quicker results the injections might be made in larger amounts directly into the peritoneal cavity. If this were done, however, a certain percentage of the test animals would probably die from acute septic conditions, the mortality from this cause depending on the virulence of the associated infection. It is to be hoped that further experiments will show that the gopher possesses the same happy susceptibility to other diseases as he displays toward tuberculosis.

**Mammary Syphilis, with Involvement of the Axillary and Supraclavicular Glands Simulating Cancer of the Breast.**—A case is reported by E. Beer, whose patient was a married woman of thirty-five years. Four months previously to coming under observation she had noted a mass in the left axilla and a few weeks later a similar mass in the upper half of the left breast. When seen there were noted also other nodular enlargements above the left clavicle, in the right axilla and above the right clavicle. The diagnosis of cancer was naturally suggested, but the masses were everywhere softer than cancer, the masses adjacent to the breasts were unusual in such a condition, while it was found that the posterior cervical lymphnodes was also enlarged. Syphilis was thought of, and this suspicion was confirmed by a pretty positive though meager history of specific infection. Consequently mercury was given hypodermatically and the iodides were given internally in increasing doses. In one month the breast had become normal and the general condition had in every way improved. In another month nearly all the glandular swellings had disappeared.

*American Medicine, October 28, 1905.*

**Certain Complications and Sequels Met in Operative Cases of Laryngeal Diphtheria.**—B. Franklin Royer attributes sudden death during attempts to intubate in certain cases to reflex apnea. A cause of acute stenosis after extubation not usually given he proves to be atony of the cricoarytenoidei postici muscles. Autoextubation he believes is caused by pressure paralysis of the cricoarytenoidei laterales. Case histories are given typical of many complications with illustrations of ulcers due to pressure sloughs or trauma. One illustration shows a condition not previously described. This histological study of a section of a larynx almost closed by chronic stenosis shows infiltration of the perichondrium with cartilage cells thus tending to make stricture a cartilaginous one. In considering the treatment Dr. Royer says but little can be done for reflex apnea. The courses of treatment open for the other conditions are: (1) Persist with intubation; (2) insert large tubes, allowing them to remain for long intervals of time; (3) when autoextubation becomes dangerous and large tubes are not retained, do tracheotomy; (4) intubate frequently while the tracheotomy tube is being worn in order to prevent stricture stenosis; (5) with chronic stenosis due to contracting scar tissue, practise wide dilation with persistent intubation; (6) consider Röntgen-ray treatment as a possible adjunct in softening scars causing chronic stenosis; and (7) avoid, if possible, tracheotomy as a means of curing a patient of a tube habit.

**Frequency and Etiology of Acute Nontuberculous Pneumonia in a General Hospital.**—William Travis Howard, Jr. based his study upon a series of 550 consecutive autopsies, which cover a period of about seven years. All doubtful cases and all cases of simple bronchitis are excluded. The diagnosis in every case is based upon microscopic as well as macroscopic examination. The pneumonias are classified according to the usual custom into croupous or lobar, and broncho or lobular. The 550 consecutive autopsies furnish 195 instances of acute non-tuberculous pneumonia, an incidence of from 35 to 45 per cent. Of these cases 76, or about 61 per cent. occurred in individuals with acute infectious processes. Of 43 autopsies in typhoid fever cases in this series, in 22 there was bronchopneumonia and in 5 croupous pneumonia. Of 81 patients with peritonitis from all causes, 36, or 44.4 per cent. had pneumonia.

**Hyperchlorhydria.**—J. A. Lichty asserts that about one-third to one-half the patients suffering from digestive disturbance have hyperacidity. Not all cases of hyperacidity are necessarily of the class designated hyperchlorhydria. Patients with hyperchlorhydria are usually neurotic, and these cases do not yield rapidly to treatment. They differ in this respect from cases of chronic gastritis, which may have a hyperacidity in the early stage of the disease, but later develop a subacidity. The diagnosis of hyperchlorhydria should be made only after chronic gastritis, ulcer of the stomach or gallstone have been absolutely excluded. It is not possible to make an absolute diagnosis without examining the stomach contents. This must often be done several times. In considering the treatment it is necessary to recognize at least two classes of patients. One class includes those advanced cases in which there is usually a splanchnoptosis, a dilated stomach, emaciation, and prominent nervous symptoms. In these cases an absolute or modified rest treatment is indicated and will accomplish most satisfactory results. The other class includes those early cases in which the patients are still well nourished and have scarcely any symptoms but those referred to the stomach. They are usually relieved without adopting any extreme measures.

*Journal of the American Medical Association, Oct. 28, 1905.*

**The Ocular Origin of Migraine.**—George M. Gould notes the confusion that exists in regard to the conception of migraine in the literature and is especially severe on the neurologists and others who have not accepted eyestrain as its general prevailing cause. Of all atypical diseases, he says, migraine is, by all odds, the leader. This is, first, because its cause, eyestrain, is of a thousand different kinds and intensities, and second, because vision is so bound up in some way with almost every physiological activity, every psychic and bodily function, that the symptoms produced by its derangement are most multiform. The infinitely varied morbid cause or seed is planted in an infinitely varied soil. He gives the history of the eyestrain theory of its causation, and quotes from a large number of writers who have reported cures of the condition by correction of ocular defects by proper fitting of glasses. He says: "I could give the details of perhaps a thousand cases of 'migraine' or sick headache cured by glasses. I should say that 90 per cent. of cases are immediately curable, and a large proportion of the rest curable in time, and as soon as the secondary systemic functional effects have been overcome. A few cases are incurable, because these secondary effects have become organic or too chronic to allow any cure. There are also rare cases in which mental reaction has become impossible."

**Respiratory Movements of the Bronchi.**—Incited by observations in patients of active movements during operations, E. F. Ingals has investigated the subject experimentally on animals and in the literature. He finds that there is a regular respiratory movement of the bronchi during respiration, most marked in the larger tubes in young animals, and gives clinical observations bearing on the action of the bronchial muscles in the

production of the physical signs and their modifications, supplementing these by reports of experiments on dogs. He thinks the action of remedies may be profitably studied through the bronchoscope on the living animal and refers to the statements and findings of Einthoven and of Dixon and Brodie bearing on this point. His studies are not yet completed.

**The Psychoses of Heart Disease.**—W. House calls attention to the mental disturbances associated with cardiac disease, which, he thinks, have been rather neglected by authors of text-books, the heart disease being regarded either as a complication of the insanity, or, the organic symptoms predominating, they either overshadow the slight mental ones or so disable the patient that he can be readily cared for in the wards of a general hospital where psychic derangements are considered as only secondary and subordinate to his bodily ailment. In the severer cases this may do no harm, but in the slighter ones it is bad, as the mental disorder which should be attended to is likely to be overlooked. He recognizes four principal types, more or less shading into each other, as follows: 1. Panicky conditions alternating with some depression and irritability, without active delusions or hallucinations. In such cases the patient is usually terrified by the consciousness of cardiac sensations and irregularities. 2. Delusive symptoms based on misinterpretations of local cardiac phenomena, such as pain. 3. Active hallucinations and delusions from circulatory disturbances involving sensory organs. 4. Dementias from secondary lesions of the brain. Case histories illustrating the different types and the relation of the heart lesions to the mental symptoms are given. It is not contended that the heart disease was the sole cause in every case, but rather that it was the exciting cause, except wherein the cardiac troubles were rather the effect, and especial emphasis is given to the relationship of mental improvement to the treatment directed to the heart trouble. During a residence of nearly two years in a large state hospital the author observed but few of these cardio mental cases, and the inference is that they are more often treated by the internist than by the alienist, and their psychic side has thus been minimized.

**Typhoid Perforation.**—From a study of the subject, R. H. Harte concludes that perforation is a much more common accident in typhoid fever than is generally supposed, it being the cause of death in one out of every three or four fatal cases. It occurs most frequently between the fourteenth and twenty-first day of the disease, and does not appear to be more common in the severest than in the mildest types of the disorder. The ileum is its most frequent site, the majority of perforations occurring within from 12 to 18 inches of the ileocecal valve. The next most common localities are the appendix and the cecum. In a large percentage of cases, pain is present, though it may be only transitory. In about half the cases the onset is sudden, severe, and with increasing intensity, localizing itself in the right iliac fossa. Tenderness and rigidity are present to a greater or less extent in all cases. The latter, Harte considers a most valuable sign, never absent except in patients with very large and pendulous abdomens. If perforation is suspected, the temperature should be taken every hour to verify any marked variation in this symptom. Distension is a late symptom, usually noticed some hours after the perforation has occurred. Obliteration of liver dullness is not regarded as a reliable sign. The study of the leucocytes is of little use, though occasionally their increase may make the diagnosis more positive. The differential count is of no practical value. Before making a positive diagnosis, pain caused by pleurisy, pneumonia, cholecystitis, acute gastrointestinal indigestion, iliac thrombosis, appendicitis, peritonitis, renal calculus, distended urinary bladder, or even a hemorrhagic exudate into the abdominal muscles must be carefully considered, as any of these may simulate perforation. Nature may sometimes close perforations, but the only rational course when they occur is surgical intervention. No case is too desperate for operation, as the worst are sometimes saved. In case of doubt, when symptoms point to perforation, the safest course is to operate. Even when no perforation is found, patients, as a rule, seem benefited by operation. With the diagnosis once made, Harte knows of no other condition, except possibly hemorrhage, in which speed in operating is so important, as in this. Everything should be prepared beforehand so that there may be no delay when once the knife is taken in hand.

**A Philippine Fever.**—Two cases of a somewhat temporary febrile affection suggesting typhoid or malaria and the discovery of a peculiar organism associated with it are reported by H. D. Bloombergh and J. Morgan Coffin. The fever was accompanied with general malaise and in one of the cases with marked muscular pains. It started with chills, but sweats were lacking. The organism was found in the red blood cells. It is a motile hemocytozoon, approximately 2.5 microns long one micron broad, unpigmented, and refractive like the malarial parasite. Its movements are of two kinds, the first depending on its rotation on one or other of its two axes, and the other an independent movement from one position to another within the cell. The motion ceased after several hours' observation and in specimens kept over night a few narrow ring-shaped bodies were found. This parasite was probably first described by Asst. Surgeon H. M. Smith, U. S. A. (Surgeon General's Report, 1904), and the reason it has not been more generally recognized in the peculiar transient fever that occurs in some portions of the Philippines without the presence of the malarial parasite, is its small number in the blood. Smith's cases were reported under the head of estivomalarial fever though he remarks on the peculiarities of the organism and its possible distinctness.

*The Lancet, October 21, 1905.*

**Total Alopecia Following the Use of Cantharides.**—A man who had on his head a patch of what appeared to be tinea, was directed by P. F. Barton to apply the B. P. liquor vesicatorius. About one week later the patch treated became surrounded by a swelling which, in the course of a week, extended over the entire scalp and face, which pitted deeply on pressure. In two days more there was a slightly raised rash from head to foot, and blood in the urine. In the course of a few weeks the hair began to fall out, first on the head, then on the body, involving the axillary and pubic regions, until it was entirely lost. Later the nails fell off. Eight months later the nails had reappeared but there was no sign of returning hair. The general health had been poor all the time. The hair bulbs had not been destroyed and it was expected that the hair would grow in due time. Both before and after this particular case the bottle of liquor vesicatorius had been in constant use and with perfectly normal results.

**The Pathology and Prevention of Secondary Parotitis.**—This topic is considered exhaustively by R. H. T. Bucknall, who notes that secondary parotitis is distinguished from the primary disease or mumps in the following particulars: (1) It invariably occurs as a complication during the course of some other malady; (2) it is not contagious; (3) it not infrequently suppurates. A long list of diseases is enumerated in the course of which this complication may arise, and its symptoms, course, and termination are briefly sketched. The author refers to the following theories of etiology: (1) Pyemic or embolic; (2) heat degeneration; (3) toxin excretion; (4) sympathetic; (5) diet infection. He finds that the observations of recent years tend to confirm the theory last named, and reports six personal cases as additional evidence. He concludes, therefore, that secondary parotitis is invariably due to an infection of Stenson's duct, dependent on a septic condition of the mouth, and that its onset may be prevented by attention to the following details: (1) The mouth should be carefully cleansed and rendered aseptic before operation, and at the commencement of long febrile illnesses; (2) the anesthetic apparatus should be sterile; (3) the mouth should be regularly cleaned, especially after every attack of vomiting; (4) the bowels should be opened early and food by the mouth, and especially solid food, should be given as soon as possible; (5) opium should not be given unless absolutely necessary; (6) the head should not be placed too low nor the binder fixed too tightly while dorsal decubitus should be given up as soon as possible.

**On the Discrimination of "Physiological Albuminuria" from that Caused by Renal Disease, and on the Means of Checking the Albuminuria Where it Occurs Independently of Such Disease.**—This study has been made by A. E. Wright and G. W. Ross. Their technical methods are described. The discrimination between the two forms of albuminuria is estimated on the basis of the "excretory quotient," which is an expression of renal efficacy obtained by dividing the salt content of a patient's blood into the salt content of his urine. The quotient is arrived at by collecting from a patient who has just emptied his bladder a sample of blood and as soon afterward as may be possible a sample of urine. Progressive dilutions are made of the serum and urine thus obtained, and each of these solutions is mixed (by a method described in the paper) with blood in the proportion of two volumes of the diluting fluid to one of blood. The "excretory quotient" is then obtained by dividing the minimum dilution of the urine which effects complete hemolysis by the minimum dilution of the serum, producing a like result. The application of this plan to physiological albuminuria cases always shows a quotient of two or above. The same results can be obtained with healthy persons and contrast in a marked

manner with those derived from cases of renal disease. The condition in physiological albuminuria arises from a lymph transudation into intact urinary tubules. This supposition wins support from the consideration that the conditions which are favorable to the occurrence of serous hemorrhage in general—to wit, increased hydrostatic pressure in the capillaries of a particular region, and diminished blood coagulability—are favorable also to the appearance of albumin in the urine in the cases we have here in view. The authors state that the appearance of albumin in the urine in physiological albuminuria is influenced by active exercise, by nervous disturbances, and by the assumption of the erect posture; and we may note that under all of these conditions the hydrostatic pressure in the renal capillaries would be increased. They further recall the fact that a condition of diminished blood coagulability was found in many of our cases of physiological albuminuria; and that the output of albumin in cases of physiological albuminuria can, as is shown in the next section of this paper, be restrained by increasing the coagulability of the blood. It must be left for future experiment to determine whether in physiological albuminuria, as in urticaria, the exudation can be increased by the ingestion of decalcifying and lymphagogic agents. They further believe that the use of the calcium salts to increase the coagulability of the blood will also check the output of albumin in these physiological cases. They refer to the practical bearing of all these observations on the matter of candidacy for life insurance, and summarize by saying that when it is found that a patient possesses a normal excretory quotient, and that his albuminuria can be abolished by diminishing the hydrostatic pressure on the renal capillaries and by increasing the coagulability of the blood, there is every reason to conclude that the kidney is free from organic disease and that life is no more endangered than it would be if the patient were the subject of urticaria.

*British Medical Journal, October 21, 1905.*

**A New Operation for Moderate Short Sight.**—Ernest E. Maddox tried the pressure-massage treatment on a boy, sixteen years old, with only temporary benefit. The patient was training for Woolwich, but failed to pass his examinations on account of his ocular defect. After repeated requests from the boy, the writer undertook the operations which he had suggested. These consisted in flattening the cornea, first in one meridian and then at right angles. Without chloroform, the writer began with the most difficult meridian, namely, the horizontal. He first dissected up a conjunctival flap, and threw it over the cornea. He then introduced a triangular iridectomy knife between the reflected conjunctiva and the sclera, and entered the anterior chamber. The operation was extremely delicate, for the peripheral nature of the incision in the very nervous and mobile eye, made the iris prolapse again and again, especially after the incision was enlarged above and below with a probe-pointed knife, which was the next stage of the operation. Only a very large incision is capable of producing a regular flattening of the cornea. At last the iris was reposed and the conjunctival sutures inserted so as to exert considerable traction on the flap. Healing was painless and uneventful. The second operation was far simpler than the first. The incision was made with an ordinary cataract knife, downward. The healing was equally successful. The patient, after a term of study, successfully passed his examinations.

**Remarks on the Pathology of Bradycardia.**—John Hay gives the history of a patient who was healthy until he was twenty-six years old, when he suddenly lost consciousness. He complained of "breathlessness on exertion and attacks of unconsciousness." Later he suffered from extreme cardiac failure. The writer noted the following facts: The apex beat was situated well outside the nipple line, slow, heaving, and forcible in character, twenty beats per minute. Pulsations or small beats, numbering fifty or sixty per minute, occurred regularly over the third left interspace, just to the left of the sternum. Synchronous pulsations occurred in the veins of the neck. Definite systolic retraction in the third, fourth, and fifth left spaces were noted. Cardiac dullness (deep) extended seven inches to the left, and two inches to the right of the middle line. A systolic murmur was heard at all areas, loudest and harshest over the cornu of the right ventricle. It was conducted to the left and well heard along the vertebral border of the scapula. No sounds were audible accompanying the small pulsations mentioned above. The pulse varied from seventeen to thirty per minute. Auricular contractions occurred twice or thrice as often as the ventricular, the cause of the bradycardia being "heart block." Examination of the heart after death showed two marked changes besides the hypertrophy and dilatation of the chambers. Stretching of the auricular canal (the part normally within the auriculoventricular groove), and separation, or rather attenuation of the bond between the bases of the valves (tricuspid) and base of the ventricle. The writer states that normally the ventricle responds to a stimulus spreading down to it from the auricle; if by any means the ventricle is cut off from this normal periodic stimulus it tends to initiate its own stimulus and to take on a rhythm different from, and independent of, the auricle. The term "heart block" is applied to this condition. When the stimulus for ventricular action arises in the ventricle itself, there is a slow rhythm. The result of "heart block" is consequently a bradycardia. In this case the writer believes that the block occurred at the attenuated part of the ventricular wall situated at the base of the ventricle at its junction with the auricular canal. He thinks that the dizziness and fainting were due to a temporary cessation of ventricular contraction.

*French and Italian Journals.*

**Necessity of the Examination of the Ears and Rhinopharynx of School Children.**—Armand Lévy, from his extensive work in this line is greatly impressed with the necessity of these examinations. He calls attention to the importance of breathing freely through the nose. Only too true is the saying that when the nose is stopped in infancy the ears will be closed in old age. Statistics show that a large number of children suffer from lesions more or less closely associated with the auditory and the respiratory apparatus. These lesions are too often ignored. The writer has had occasion during the last year to examine systematically seven hundred and ten school children between the ages of four and thirteen years inclusive. Intervention was indicated in the following various cases: Seventeen children had hypertrophy of the tonsils; forty-four, adenoids; five children were affected with both of these lesions; one had dry pharyngitis. Fifty-four children were troubled with wax in one ear; nineteen in both ears; eight had suppurating middle ear trouble; of these, one had perforations; thirty-two other children presented various lesions of the middle ear more or less recent, while one had internal ear trouble. In other words, 26.9 per cent. of these children suffered from lesions of the ear and rhinopharynx.—*La Presse Médicale*, September 27, 1905.

**Treatment of Articular Tuberculosis.**—A. Broca presents certain conclusions on this subject. Medical treatment is indispensable. Nevertheless a continuous sojourn at the seashore is not necessary. Superficial synovial lesions are treated by injections of a ten per cent. solution of iodoform in ether and by relative immobilization of short duration. Osteoarthritis is treated by complete immobilization in the position indicated. Immobilization is the basis of treatment of these lesions, although one may have recourse to various adjuvants. Operation will prove exceptional. Resection is preferable to synovectomy. Suppurating white swellings should be subjected to puncture and to injections of iodoform and ether. The writer does not favor very strongly irritating injections. The dangers of infection call for generous openings of the bony foci with drainage. The correction of faulty positions should be made only after every infectious focus is suppressed. Immobilization should be discontinued only after the disappearance of all pain, whether spontaneous or not. Too great effort to move the joints should not be made.—*Gazette des Hôpitaux Civils et Militaires*, September 23, 1905.

**The Treatment of Tics by "Reeducation."**—Beutter declares that the only rational treatment in the case of tic is "reeducation." Tic, as Brissaud has shown, is preeminently a motor disorder due to a defect in cortical control,—to an insufficiency of volition. The principle of Beutter's method consists in gradually bringing into control the muscles which have been acting involuntarily. This control is both positive and negative; that is, the patient decrees that these muscles at times shall be active and at other times quiescent. In order to attain this end it is necessary that the subject learn to maintain a "photographic" immobility of progressively increasing duration. When the patient has reached the point where he can voluntarily reproduce his tic he has become master of it, and is cured. These exercises are taken daily at certain hours under the direction of a physician or an intelligent person. At times the patient may practice by himself before a mirror. If any cause of this affection be discovered, it must be treated besides. This method of treatment has been followed with the happiest results in these unfortunate cases. *La Presse Médicale*, September 23, 1905.

# Book Reviews.

Diseases of the Anus and Rectum. By D. H. Goodsall, F.R.C.S. (Eng.), Senior Surgeon to the Metropolitan Hospital, late Senior Surgeon to St. Mark's Hospital for Fistula and Other Diseases of the Rectum; and W. Ernest Miles, F.R.C.S. (Eng.), Surgeon to the Gordon Hospital for Diseases of the Rectum, Surgeon to the Cancer Hospital, Brompton; late Senior Assistant Demonstrator of Anatomy at St. Bartholomew's Hospital Medical School, and House Surgeon to St. Mark's Hospital for Fistula and Other Diseases of the Rectum, etc. In Two Parts (illustrated). Part II. London, New York and Bombay: Longmans, Green & Company, 1905.

Part II. of this work is devoted in the main to the more serious surgery of the rectum—the various forms of ulceration, the benign and malignant growths, and stricture—while prolapsus, invagination, foreign bodies, pruritus, and syphilis each have a chapter. The work is distinctly well done and valuable, devoid of padding, and strictly scientific in its conception and execution, and though rather practical than original, perhaps none the less useful on that account. Attention can be given to only a few points, such as the classification of stricture as "the linear or annular stricture and the tubular stricture," which is decidedly more practical than scientific. The practical division of carcinoma into "those cases in which extirpation is praticable and those in which it is not" cannot be too highly recommended to the practitioners of to-day, and the various operations are well described. We cannot forbear quoting the following as showing the gradual triumph of scientific observation over prejudice and ignorance: "We have already mentioned that a large number of strictures of the rectum are set down as syphilitic when they are really due to infective ulceration, and have given our reasons for this opinion. Still there are many observers who support the opinion that the condition known as the *syphilome ano-rectal* of Fournier is the most frequent cause of stricture of the rectum. To our minds, this opinion has been based entirely upon the analogical reasoning that because syphilis produces connective tissue hyperplasia in other organs, it must necessarily do so in the rectum. . . . Though we do not deny that such a form of stricture may exist, we nevertheless state that we have never seen an instance in which the syphilitic origin of a stricture was beyond dispute."

Exercises in Practical Physiology. By Augustus D. Waller, M.D., F.R.S. Part II. Exercises and Demonstrations in Chemical and Physical Physiology. By Augustus D. Waller and W. Legge Symes. London, New York, and Bombay: Longmans, Green & Company, 1905.

The title exactly describes the contents of this little book. The subjects treated are: The Blood, Circulation, The Carbohydrates and Salivary Digestion. The Proteids and Gastric Digestion, Fat and Pancreatic Digestion, Milk, Bile, Muscle, Urine, and Respiration. There are numerous illustrations and tables and the book should prove useful in the physiological laboratory.

The Eye. Its Refraction and Diseases. Diseases of and Operations upon the Eyeball and Its Adnexa. By Edward E. Gibbons, M.D., Assistant Surgeon of the Presbyterian Eye, Ear, and Throat Hospital; Demonstrator and Chief of Clinic of Eye and Ear Diseases in the University of Maryland, Baltimore. Vol. II. New York: The Macmillan Company, 1905.

The concluding volume of this treatise is one of 632 pages. It is beautifully printed and fairly well illustrated although the views of the fundus oculi that have been inserted are hardly up to the standard that we expect in such a work. Sufficient and well-chosen illustrations enhance the value of a work on diseases of the eyes that is intended, as this one is, to be used by the student and general practitioner.

The text is divided into twenty-five chapters, of which the first three are devoted to "Embryology and Anatomy." These are followed by a chapter on the "External Examination of the Eye." The diseases of the different parts of the eye and its adnexa are then considered in proper order. Then follow chapters on "Ophthalmic Migraine," "Associated Diseases of the Eye and Ear," "Eye Lesions in General Disease," "Operations on Animals' Eyes Methods of Preserving Eye Specimens." The descriptions of ocular conditions are brief and to the point. Authors are quoted, but there is no bibliography. The text evidences a wide knowledge of the theory of ophthalmology and of clinical ophthalmology as practised by others, but discloses a lack of personal experience. The treatment of that portion of ophthalmology which has to do with physiological optics can be accomplished satisfactorily and creditably by one whose practical experience is limited, but clinical ophthalmology, as clinical medicine, can well be written of only by one whose personal experience has been extensive.

The work is commendable in that it gives evidence of much study on the part of the author but it presents nothing in advance of works already published.

A Manual of Organic Materia Medica and Pharmacognosy.—An Introduction to the Study of the Vegetable Kingdom and the Vegetable and Animal Drugs, comprising the botanical and physical characteristics source, constituents, pharmacopeial preparations, insects injurious to drugs, and pharmacal botany, by Lucius E. Sayre, B. S., Ph.M. Third edition, revised. With Histology and Microtechnic by William C. Stevens. With 377 illustrations. Philadelphia: P. Blakiston's Son & Co., 1905.

Part I. of this book of nearly 700 pages gives a classification of drugs wherein are given physiological action and therapeutic application, titles of the newer remedies with structural formulas, properties, and dose, maximum and minimum, a list of synonyms, sources, characters etc.

Part II. gives a description of organic drugs derived from the vegetable kingdom arranged according to familiar or natural orders. This is the most valuable part of the book, as it gives sources, varieties, description, adulterants, constituents, action, and uses. This portion of the book has been rewritten, and a description of a large number of the newer remedies has been added. One prominent feature of this part of the work is that only those remedies are presented which are prescribed and dispensed to any considerable extent by physician or druggist. Minimum and maximum doses are given rather than an average, as in the last pharmacopeia.

Part III. gives a description of insects injurious to drugs, while Part IV. gives the elements of plant histology and microtechnic, a thoroughly interesting and instructive section, especially to the druggist. The chapter on powdered drugs has been rewritten, and gives information which will be of great interest to students and instructors in schools of pharmacy. The illustrations are abundant. Finally, a copious index is given with cross references—a feature to be commended in books which treat of such a variety and number of subjects. The classification is up to date, but would be found complex and tedious were it not supplemented by the copious index.

The Medical Epitome Series. Practice of Medicine. A Manual for Students and Practitioners. By Hughes Dayton, M.D., Principal to the Class in Medicine, New York Hospital, Out-Patient Department; Clinical Assistant in Medicine, Vanderbilt Clinic, College of Physicians and Surgeons, Columbia University. Series edited by Victor Cox Pedersen, M.D. New York and Philadelphia: Lea Brothers & Company. 1905.

This little manual is the latest volume of the "Epitome Series." By the exclusion of diseases of the nervous system and of the larnyx and pharynx, sufficient space has been obtained to treat the more important of the infectious diseases at greater length and in more detail than is usually done in books of this class. As a rule the student will find all the essentials of any given disease, including definition, chief synonyms, etiology, pathology, symptoms, diagnosis, complications, prognosis, and treatment.

Practical Massage in Twenty Lessons. By Hartvig Nissen, Instructor and Lecturer in Massage and Gymnastics at Harvard University Summer School; Director of Physical Training, Brookline Public Schools; Author of "Swedish Movement and Massage Treatment," "A, B, C of Swedish Educational Gymnastics," "Rational Home Gymnastics," etc. With 46 original illustrations. Philadelphia: F. A. Davis Company, 1905.

This is a simply written but thoroughly practical manual of massage. The first ten lessons contain instructions for the various manipulations suitable for different parts of the body, the eleventh lesson considers general massage as a substitute for exercise, and the remainder of the book is devoted to the application of massage in the morbid conditions susceptible to this form of treatment. The descriptions are concise, but adequate; the illustrations make up in clearness for what they lack in execution, and the true function of massage as a secondary but not a primary therapeutic agent is kept constantly before the reader. A little more space might with propriety have been allotted to the discussion of massage in sprains and fractures in view of the important part that this treatment now plays in such conditions; but, as a whole, the book is very satisfactory, and may be recommended to those who do not require one of the larger works.

*Thirty-first Annual Meeting, Held at Indianapolis, Indiana, October 10, 11, and 12, 1905.*

THE PRESIDENT, DR. BRANSFORD LEWIS OF ST. LOUIS, IN THE CHAIR.

(*Concluded from page 721.*)

**The Present Status of the Surgery of the Stomach.**—Dr. W. D. HAGGARD of Nashville delivered this, the address in surgery. A discussion relative to operation for stomach lesions now was similar to that in regard to appendicitis twelve or fifteen years ago. Then only the desperate cases were submitted to operation; it was so now with many stomach cases. This, however, must yield to the logic of results, and in a short time the profession generally would advise early operation as they now well-nigh universally did in appendicitis. Improved technique, low mortality and satisfactory end-results would inevitably do away with the empirical treatment of occult intractable stomach troubles. The typical indication for operative interference was obstruction of the pylorus from an open or cicatrized ulcer causing dilation of the stomach, with stasis of food. The short-circuiting operation of gastroenteric anastomosis found its ideal indication here, and had given the most beneficent results. It was the *fons et origo* of the present group of drainage operations, as well as other gastric procedures, and was altogether the most perfected and satisfactorily employed operative device. The other complications of ulcer requiring operation were pointed out as (1) perforation; (2) hematemesis of chronic ulcer; operation was advised in repeated acute hemorrhage or in constantly recurring small hemorrhages. Other indications were found in the following groups of cases; (3) obscure and persistent stomach symptoms with a long history of dyspepsia culminating in hemorrhage, after it had been controlled by medical means and the patient put in the proper condition for operation; (4) cases of chronic intractable dyspepsia, even without dilation, which failed to yield to proper medical treatment, and were not due to a general visceral ptosis. Aside from malignancy, chronic ulcer and its complications furnished most of the indications and the majority of cases. It was not impossible that the bulk of cases of inveterate dyspepsia was really due to ulcer. That it was found post-mortem so very many more times than it was recognized clinically was a reproach not so much to diagnostic measures as to failure to properly apply them. Dr. Haggard quoted Moynihan as saying that he did not know any operation in surgery which was more successful or which was attended by better or more striking results than gastroenterostomy for chronic ulcer of the stomach. It was in duodenal or pyloric obstruction that gastroenterostomy found its most striking indication and attained its highest efficiency. The many various methods for performing gastroenterostomy gave a feeling of wonder at the ingenuity displayed. The relative safety of the operation even by varying technique was illustrated by Robson's results, namely, over two hundred cases with a mortality of 3.6 per cent. The posterior operation had largely supplanted the anterior, because of the avoidance of the loop around the transverse volon and the mischief it caused. The anterior operation was reserved for malignancy, where the speediest technique was the best, where the stomach could not or should not be delivered freely and the operation was palliative in its intent. The Murphy button could be employed in gastric and intestinal surgery on account of its rapid insertion; while the McGraw elastic ligature found its best scope in such cases if an immediate opening was not required. The posterior operation without the loop, with a longitudinal incision from one to three inches from the duodenojejunal angle, gave almost complete immunity from the vicious circle. A most logical operation for gastric ulcer was that proposed by Rodman of excising the ulcer-bearing area by a pylorectomy. This stopped the possibility of hemorrhage, removed the lesion and cicatrices. This removed also all of the ulcers, as they were usually multiple, and situated in the antrum pylori, which was also the cancer site. It removed any coexisting duodenal ulcer in the first two and a half inches. The most crying need was some means for the early recognition of cancer of the stomach. Until the magic and immunizing therapy which would convert malignancy into benignancy was discovered, extirpation was the only resource in such cases. One-third of all carcinomata were in the stomach.

**Blood Poisoning Emanating from the Nose and Pharynx.**—Dr. J. HOLINGER of Chicago stated that microorganisms of the nose and pharynx were formerly considered harmless. A great many diseases could be directly traced to them. Fatal cases of blood poisoning occurred, but were not very frequent. This statement in the paper was substantiated by the histories of two cases. The speaker said that Dr. Schwarzenbach had shown that a number of general diseases, such as acute and chronic articular and muscular rheumatism, sciatica, etc., could be traced directly to general infection from the pharynx with streptococci. He proved this statement by showing that with the decrease in the number of streptococci in the pharynx all general symptoms diminished and disappeared. He had the advantage of practising in the mountains, where these infections were only sporadic and epidemic. In the city these were constant, general, and endemic. The connection between acute rheumatism and tonsilitis was well known. The tonsil received its lymph from the nose and pharynx and might therefore become secondarily inflamed in cases of infections located in the nose and pharynx. There was a difference in the course of the disease, whether the infection dated from the nose and pharynx, or directly from the tonsils. The most striking example was diphtheria. All know the seriousness of diphtheria starting from the tonsils and the lymphatics of the nasopharynx, while diphtheria of the nasal mucous membrane was a rare but comparatively innocent disease. Histories of cases were given by the author where chronic rheumatism of many years' standing, which had been treated with all kinds of medicine, massage and *x*-ray, disappeared when the suppurative processes in the nose and its sinuses were cured. The mixed infections of tuberculosis of the lungs and bones might be avoided, in the opinion of the author, if the pharynx and nose, whence they started, were treated. The treatment was simple; very little was accomplished by sprays. Washes with boric acid solution were used in the nose, and in the pharynx paintings with solutions of iodine in iodide of potassium and glycerine. Difficulties were often experienced in locating a suppuration of the nose or nasopharynx; then the experience and skill of the specialist came to the rescue.

**Cancer of the Rectum.**—Dr. E. B. SMITH of Detroit, Mich., pointed out the recognized radical operations required in cancer of the uterus and cancer of the breast, saying that to the practical working surgeon when operating it mattered not so much whether the cancer was due to a parasite or to a tissue fault as it did to feel and to know that all tissue involved was being extirpated. The modern treatment for cancer consisted of the following: Internal medication of arsenic, *x*-ray, local application of arsenic and zinc, Coley's fluid—the mixed toxins of the streptococcus of erysipelas, and the bacillus prodigiosus; resection of nerves at the site of malignant neoplasms; ligation of blood-vessels supplying blood to the parts, and extirpation. The author made a special plea for extirpation in the treatment of cancer of the rectum as being the only procedure that would give hope of a cure. He touched on colotomy as the operation of necessity rather than the operation of choice, and urged an examination in all cases where the rectum was involved, as in cases of hemorrhoids, where there were bloody stools, where there was painful defecation, and where there was

constipation, and advised a microscopical examination in all cases when a neoplasm was discovered. The author showed that the extirpation of a part or the whole of the rectum by the Kraske method was the ideal operation, but should be practised only by those who have had experience in capital operations.

**The Surgical Management of Injuries of the Peritoneal Viscera Resulting from Violence Applied to the Abdominal Wall.**—Dr. John Young Brown of St. Louis, Mo., called attention to the dismal mortality in such cases, and emphasized the importance of their early diagnosis and prompt surgical treatment. He reported a series of six cases which had come under his personal care during the past eighteen months, in all of which abdominal resection was done. Of the six cases one recovered and five died. An analysis of the cases led to one conclusion, namely, the importance of early diagnosis and prompt surgical treatment by abdominal section in all cases of abdominal contusion, in which there were present the slightest symptoms pertaining to injury to peritoneal viscera. If one waited until the classical symptoms of peritonitis were present surgery promised little.

**Intraperitoneal Tuberculosis.**—Dr. F. F. Lawrence of Columbus, Ohio, read a paper on this subject, in which he drew the following conclusions: (1) Intraperitoneal tuberculosis is frequently a local disease; (2) it probably occurs much more freqently in the female than in the male; (3) in a large majority of cases it is primarily visceral and the general peritoneum is secondarily involved; (4) the surgical treatment is rational, sometimes agreeably surprising in results, and again bitterly disappointing; (5) in this, as in many other surgical conditions, early diagnosis and early operation will bring more certain results; (6) in this condition the greatest obstacle to overcome is the idea that it is a secondary condition; (7) no case of intraperitoneal tuberculosis should be denied the benefits of operation, no matter how extensive, so long as there is no positive pulmonary or pleuritic involvement, for the reason that some apparently hopeless cases fully recover; (8) when there is a tubercular peritonitis, a sequel of tubercular tubes, ovaries, or appendix, the primary focus should always be removed; (9) in these tubercular cases the mesenteric glands have not been fond frequently involved, and when they are operation accomplishes very little good; (10) in tubercle of tubes and ovaries the adhesions are usually firm, sometimes, though not usually, very vascular, and not infrequently involve loops of the small intestine; hence the greatest care is necessary, to avoid serious injury to bowel, and at the same time separate completely all adherent surfaces and provide complete drainage; (11) drainage is the great factor in recovery, when properly carried out.

**Pyloroplasty with the McGraw Ligature.**—Dr. J. Henry Carstens of Detroit said that many cases with disturbances of digestion could not be diagnosticated or relieved by medication. These should be subjected to an exploratory celiotomy. Gastroenterologists should not treat patients for months and years if they could not make a positive diagnosis or cure the patient. After reasonable efforts the patient should be sent to the surgeon for relief. The McGraw ligature was a valuable means of relieving stricture at the pylorus and the resulting dilatation of the stomach. This method of operating was easy and quick; the danger was very small, and the operation was preferable to those heretofore used in benign contractions at the pylorus. It was a great deal better than gastroenterostomy, as one restored as nearly as possible the normal condition. Quite a number of gastroenterostomies had been reported, with a most gratifying result in some of the cases, but the difficulties encountered, the trouble with the vicious circle frequently called for a double operation. The McGraw elastic ligature method should be the operation of choice. He concluded by saying that (1) many stomach troubles were due to mechanical means; (2) these cases could only be relieved by surgery; (3) many cases could not be properly diagnosticated in the present state of our knowledge; (4) obscure cases that had been subjected to various modes of treatment without benefit should receive the benefit of an exploratory celiotomy.

**Ovarian Cystoma.**—Dr. L. P. Luckett of Terre Haute, Ind., reported a case of ovarian cystoma upon which he had operated. The tumor originated from the left ovary, was attached by a broad pedicle which was tied off in sections. The uterus and right ovary were found to be normal. The fluid and tumor were estimated to have weighed between seventy and eighty pounds. The patient made an excellent recovery.

**Surgical Treatment of Nephritis.**—Dr. Alexander Hugh Ferguson of Chicago presented a further report on the surgical treatment of this disease. He reported seven cases upon which he had operated, with two deaths.

**Vesicovaginal Fistula.**—Dr. Maurice J. Rosenthal of Fort Wayne, Ind., discussed the subject of closure of ureterovaginal and vesicovaginal fistulæ, and reported a case. He concluded by saying that a considerable area of scar tissue and vaginal mucosa might be inverted into the bladder without producing ill effects. Ureteral fistula embedded in scar tissue might be inverted into the bladder and continue to discharge its urine without becoming stenosed. Even large vaginal fistulæ, where part of the bladder walls were lost in scar tissue from a previous hysterectomy, might be successfully operated by the operation of denudation and suture through the vagina without disturbing the relations of the bladder or any adhesions of pelvic viscera which might have formed in the scar.

**Sprained Ankle.**—Dr. Robert Carothers of Cincinnati read a paper on this subject, in which he drew the following conclusions: (1) No one is exempt from a sprained ankle, although some are more prone to it than others; (2) that in severity a sprained ankle will range from a trivial accident to one of extreme severity and everlasting; (3) that the outer side more often than the inner side of the ankle is the seat of trouble; (4) that the diagnosis which is ordinarily made with ease is at times made with difficulty, and occasionally an *x*-ray examination is required to make the diagnosis certain; (5) that the treatment by immobilization with a plaster-of-Paris cast is unsatisfactory, and at times injurious; (6) that the treatment instituted by Cotteral, the so-called adhesive plaster strappings, advising and urging the patient to walk on the injured foot, the early removal of these straps, followed by massage, gives the most satisfactory and best results; (7) that the old cases are to be, under anesthesia, converted into acute sprains and treated in the same manner.

Dr. David C. Peyton of Jeffersonville, Ind., reported an interesting case of pyemia following an operation for appendicitis.

**Appendicitis.**—Dr. R. E. Haughton of Richmond, Ind., followed with a paper on the history, differential diagnosis, pathology, etiology, and medical and surgical treatment of this disease. He presented a brief history and plea for an abatement of the use of the knife in place of treatment by remedies, in view of the statistics and results.

**Shall the Profession or the Laity be Responsible for the Death Rate in Appendicitis?**—Dr. J. C. O'Day of Oil City, Pa., said that every physician, when confronted with a case of appendicitis, should frankly tell the patient the nature of his trouble; explain to him, honestly and candidly, the disposition of his disease; that no one could tell what an inflamed appendix would do, and that there was no safety till the offending organ had been removed. If the patient then decided to defer operation, he, not the surgeon, would be responsible. If this were done, he thought we would hear no more complaints of, Why did not the physician advise operation before it was too late?

**Sarcoma of the Anterior Segment of the Globe.**—Dr. O. Tydings of Piqua, Ohio, presented a brief history of a patient upon whom he had operated for the removal of melanosarcoma of the anterior segment of the globe. The diagnosis of melanosarcoma was

confirmed by reliable miscroscopists and pathologists. Five days after the removal of the tumor the patient dropped out of sight and the speaker did not see him again until the following August. There was no recurrence; the cicatrix was smooth; the lone pigmented spot, not larger than a pin point, which the author took to be the remains of an old hernia of the iris, was still present, but absolutely quiescent. The patient's vision, which, when he first saw him, was right eye, 20/40, and when operated upon 20/200; left, 20/30, was now 20/20 in each eye. So far as the author had been able to examine authorities, the case stood alone. Primary melanosarcoma of the cornea was rare. Nine cases had been reported of sarcoma of the cornea by different authorities. None of these cases, however, according to an English authority, was above suspicion.

**Extraperitoneal Rupture of the Bladder Complicating Fracture of the Pelvis.**—Dr. JOSEPH RILUS EASTMAN of Indianapolis said that injuries of the pelvic bones were attended with more or less risk to life, which did not ensue solely from the damage done to the bones themselves, but arose usually from the injuries done to the viscera of the region involved. Formerly death occurred in a large percentage of cases of rupture of the bladder. The mortality was naturally much higher in those cases in which a tear of the peritoneum made possible the entrance of urine into the peritoneal cavity. However, extravasation of urine through the pelvic connective tissue in cases of purely extraperitoneal bladder rupture also formerly caused a high mortality rate. This mortality rate had been decidedly decreased by modern methods of dealing with shock and free and rational bladder drainage. The immediate and characteristic symptoms of the injury were intense pain in the abdomen, collapse, and great irritation of the urinary reflex, with ineffectual attempts to void urine. Inability to void the urine was usually present, whether the peritoneum was torn or not. If the peritoneum was injured, peritonitis of the sthenic type developed duly. As the injury usually occurred while the bladder was full, an area of dullness and tenderness was to be found over the bladder, extending irregularly beyond the normal limitations of bladder dullness, and a large amount of bloody urine might usually be withdrawn by catheterization. In the three cases described by the author, the treatment consisted in combating shock, chiefly with normal salt solution and adrenalin, in the removal of clot, suture of the rent in the bladder, appropriate bladder drainage, rest, and the application of a bandage in such a manner as to prevent movement of the pieces of bone which were broken off.

The following papers were also read: "Note on Bone Tuberculosis, with Report of a Case," by Dr. W. W. Vinnedge, Lafayette, Ind.; "Post-Operative Acute Dilatation of the Stomach, with Report of a Case Following Nephropexy," by Dr. A. E. Halstead, Chicago; "Treatment of Tuberculosis of the Cervical Lymphatics," by Dr. H. C. Sharp, Jeffersonville, Ind.; "Visceral Ptosis; Its Surgery," by Dr. Earl Harlan, Cincinnati, Ohio; "The After-Treatment of Gastroenterostomy," by Dr. Charles A. L. Reed, Cincinnati, Ohio; "Cysts of the Mesentery, with Report of a Case," by Dr. L. G. Bowers, Dayton, Ohio; "Perforating Ulcers of the Duodenum, with Report of a Case," by Dr. M. A. Austin, Anderson, Ind.

**The Patent Medicine Evil.**—The following preamble and resolution were unanimously adopted by the Section:

*Whereas*, The medical profession keenly realizes the great and increasing public evil, moral, mental, and physical, arising out of the support given by the public press to the so-called patent medicine interests, leading to the pernicious practices of self-drugging, narcotic habituation, and alcoholic excess; be it

*Resolved*, That the Mississippi Valley Medical Association commends and frankly indorses the attitude adopted by *Collier's Weekly* and the *Ladies' Home Journal* in giving publicity in the articles by Samuel Hopkins Adams, Norman Hapgood, and Edward Bok, respectively, to truthful exposure of the nefarious practices and unscrupulous methods of the so-called patent medicine concerns

---

MEDICAL SECTION.

**What is the Present Conception of Bright's Disease?**—Dr. G. W. MCCASKEY of Fort Wayne, Ind., read a paper on this subject, in which he said that the only possible justification for the use of the term was an historical one, and while its meaning must, in a sense, change with the changing views of pathology, yet the primary groundwork which constituted the historical basis on which it stood should be kept constantly in view. He presented a brief inquiry as to the character of the group of morbid states and symptoms originally described by Bright. The investigations of Gull and Sutton on the relation of arterio-capillary fibrosis as a cause of contracted kidney were the most important steps in broadening the views entertained concerning Bright's disease. They demonstrated the systemic or hematogenous character of one clinical type of the disease, which naturally stimulated thought and investigation with reference to other types along the same lines. In spite of the advances in pathological doctrine, in spite of the mutations of opinion and classification, one could not but be impressed by the close resemblance between the views entertained to-day and those of half a century ago concerning what might be called the gross features of Bright's disease. For the purpose of a broad general view of the subject, the author divided the causal conditions into six classes: (1) The acute infections; (2) chronic infections; (3) chemical poisons introduced into the circulation, of which lead may be taken as a type; (4) the influence of cold; (5) the products of perverted gastrointestinal function, and especially intestinal putrefaction; and (6) the products of perverted metabolism.

**The Combined Method of Treatment in the Arrest and Cure of Tuberculosis.**—Dr. H. B. WEAVER of Asheville, N. C., stated, among other things, that in order to wage a successful warfare against tuberculosis and prevent its spread, the method which was pointed out by nature consisted in increasing, as far as possible, the organism. All efforts, therefore, should be directed toward that goal. As only two per cent. of tuberculous patients were treated in sanatoria, that method could not now bring the desired relief. Ninety-eight per cent. of patients were treated in their homes. Therefore the general practitioner, as remarked by Osler, was, after all, the man behind the gun in this warfare, and to him, and through him, we must look for ultimate success. Tuberculosis would only then be vanquished, when it shall have become possible to strengthen the organism and assist with specific powers which will render it immune against the disease.

**The Treatment of Tuberculous Pleurisy with Effusion.**—Dr. THEODORE POTTER of Indianapolis submitted for consideration the following propositions: (1) That the profession had gone too far in accepting the general principle and following the general practice that pleural serous effusions, unless they showed a tendency to early absorption, should be removed; (2) granting that in the majority of such cases pleurisy was the dominant feature and removal of the fluid the proper procedure, and that such removal would probably tend to arrest the pleural tuberculosis, which was usually present, nevertheless the best results ought to be obtained by dealing with each case upon its own merits; (3) in cases in which the pleurisy was the sole or dominant feature, the removal of the fluid was the proper treatment; and in proportion to the accuracy of differentiation between the pleural and the pulmonary disease would be the promise of good results by removal of an effusion; (4) in cases in which tuberculosis of the lung was evidently or probably the overshadowing feature, a conservative course as regards the removal of a serous effusion was the proper one. In some cases the fluid had best be left to nature to take care of, with the hope that

the compression, immobilization, and physiological quietude of the tuberculous lung might tend to arrest the disease. In other cases of this type the removal of the fluid should be undertaken only upon a deliberate judgment, after due consideration.

**Tuberculosis in General Practice.**—Dr. HUGH A. COWING of Muncie, Ind., said that in his relation to tuberculosis the general practitioner should exercise great care in physical examination; he should strive to make an early diagnosis; he should carry a life-saving knowledge into the tuberculous home, improve its hygiene, and teach sanitation; he should employ the pure-air treatment. The method would vary to suit the individual case and condition; he should cooperate with health boards and report cases; he should count the cost before sending the patient to a health resort; he should study health resorts and sanatoriums and visit them, if possible; he should oppose quack consumption cures, and quack doctors who "cure consumption"; he should influence the press for sanitation; he should fight patent medicines; he should expose Christian Science and kindred fads that rob the consumptive of his chance for life; he should endeavor to seek legislation for sanitary advancement; he should help to popularize the consumptive sanatorium and health farm. Membership in a society for the prevention of tuberculosis would make the physician's work more effective.

**The Management of Neurasthenics.**—Dr. H. A. RODEBAUGH of Columbus, Ohio, said that an individual became neurasthenic only after having suffered from some of the psychoneuroses, the latter having been caused by traumatism, by disturbed metabolism, or by peripheral nerve irritation. Heredity, occupation, or environment could hardly be considered etiological factors without further specification. Neurasthenia should be considered a mental rather than a physical disease. Mental symptoms often persisted after removal of all physical causes, and could only be relieved by psychic treatment. Mental hygiene was both preventive and curative. The neurasthenic should be taught that a healthy mental attitude conduced to bodily health.

**Autointoxication.**—Dr. D. L. FIELD of Jeffersonville, Ind., read a paper on this subject. After referring to the theories and definitions of autointoxication by Bouchard and others, the author said that the part played by the intestinal emunctories in the elimination of certain poisonous substances was attested by the commonly fetid stools of persons who frequented autopsy rooms. The fetid character recalled the putrid odor of the emanations from the cadaver. If poisonous products had been absorbed, an effort should be made to destroy them. The liver had the power of arresting poisons. It withdrew them from the intestines and eliminated or destroyed them. One should, therefore, stimulate its action by proper therapeutic measures. If the poisons had escaped the liver, they should be eliminated by the skin, the lungs, the intestines, and the kidneys. If all these attempts failed, one should have recourse to certain antidotes which tended to counteract the physiological effects of the poisons which menaced the system. As a striking example, he mentioned the antagonistic properties of poisons in atropine and pilocarpine. The strength of the patient should not be neglected, so that he might have time to eliminate the poisons. Sometimes it was only necessary to keep a patient alive a few minutes more in order to save him. We could not provide him with radical force, and what was required was active force. Thus one was led to administer stimulants which might awaken the forces remaining latent.

**Some Remarks on the Pathology of Epilepsy.**—Dr. MARC RAY HUGHES of St. Louis, Mo., showed that each epileptic stage had a distinct pathology, and the entire category for classification of epilepsy, including the psychical varieties, had one common pathology or gross structural change, and that this structural change, whether idiopathic or organic, had to do largely with the movements of the centrifugal and centripetal mental forces as they were found in the psychical equivalent of epilepsy—dual consciousness, obliviousness, and allied states of mental eclampsia.

**History and Treatment of Epilepsy.**—Dr. JOHN W. SELMAN of Greenfield, Ind., after recounting at length the history of this disease, said that every physician acknowledged that the great cause of epileptic convulsions was the sudden liberation or explosion of nerve force which swept everything before it. Epilepsy and other diseases might exist together, and for this reason the prognosis and diagnosis were to be carefully formed and given. January 2, 1905, a man, twenty-eight years old, was brought to him who was having epileptic seizures five and six times a week. There was no aura. Like a flash he was in hard convulsions. The general appearance of the patient indicated great anemia, malnutrition, with diarrhea. The author at once used subcutaneous injections of decinormal saline solution, with the bitter tonics and arsenic, and at the expiration of ten days a great change in his condition was noticeable, and in three months he returned home, apparently well. The causes of epilepsy were toxic, reflex, and traumatic. The treatment of the disease was as various as the disease was variable in its forms and phases, and it should in nearly all cases resolve itself into three divisions, consisting in the removal of any exciting cause, in the checking of the convulsive tendency already set up, and in the prevention of any further attacks by suitable drugs or other measures of relief. The treatment was governed largely by the case and was medicinal or operative, according to the causal factors at work. In idiopathic epilepsy medicinal means should be followed, while in a case resulting from traumatism, the depressed bone, abscess, or tumor should be removed.

**The Cigarette; Its Relation to Mental and Nervous Diseases.**—Dr. W. B. FLETCHER of Indianapolis quoted extensively from articles by physicians and prominent laymen on the cigarette habit, and said that he had sometimes asked himself if the members of the medical profession were not largely responsible for the widespread prejudice against the cigarette. It was so much easier to agree with the grief-stricken mother in assigning the cause of the loved one's downfall to the innocent habit of cigarette smoking than to say to her frankly the real cause which examination had revealed, or which had been imparted under the seal of professional confidence. In the past twenty-two years he had examined over twelve hundred cases of nervous disease and insanity brought to the Central Hospital for the Insane, or in his private practice, where the cause of the malady was given by their friends as the cigarette habit. In not one case had he reason to believe that tobacco had anything to do with the causation of the disease. They were all young men, and some of them insane without doubt. Some of them smoked cigarettes to excess, but their insanity was a cause of their excess, and not the excess the cause of the insanity. Many of them were simple cases of hebephrenia, with a cigarette attachment, so to speak. One poor fellow, sixteen years of age, and at the time in acute mania, had been severely punished by his father to "beat out the cigarette habit." After three months he recovered and proved to be an unusually bright and truthful boy. He acknowledged that he had smoked three cigarettes in his life just before his mind gave way from overwork in the harvest field. Some of the cases were tuberculosis of the brain, but he thought he was safe in saying that fully ninety per cent. were young fellows reared in idleness, who had acquired other habits of vulgar and vicious companions which were reducing their vitality and sapping their brain, and the cigarette was used as a cover by patient, parent, and friends as a scapegoat, or an excuse to hide their shame.

**A Plea for More Moral Restraint for Students in Medical Colleges.**—Dr. JOHN M. BATTEN of Downington, Penn., said there were three classes of students at medical colleges: (1) Those who had good morals, were industrious and ambitious, and had a high ideal objective point. (2) Those whose morals were questionable, were not as in-

dustrious as they should be, were lacking in ambition, and consequently their ideal objective point was only mediocre. This class of students was easily led into evil habits. (3) Those who might have plenty of means furnished them for necessary and other expenses. Their ideal objective point in life was not high. Their morals were corrupt, and they had not been taught the value of economy. This class of students schemed to do evil, and endeavored to corrupt others with whom they associated. He thought no medical college should have a charter that could not and would not provide for sufficient moral protection over the students who attended such institution.
